lighter materials, such as wood, to carry a heavier load. Wood trusses are often used when steel beams are not available, or when steel is considered too expensive.

Arch

An arch is used to support the roof when a truss cannot, either structurally or economically, provide sufficient clear floor space and/or the required vertical clearance. Aircraft hangers frequently use an arch structure.

Masonry arches are occasionally used, but are limited to a span of about 60 feet (18 meters). A braced arch is composed of steel trusses, and can span from 100 to 300 feet (30 to 90 meters). A rigid frame arch can be built with steel, reinforced concrete or wood, and can span from 60 to 200 feet (18 to 60 meters).

Cantilever

Cantilever supports are used primarily in buildings of light construction, and usually for decorative purposes. In industrial applications, they are used for some warehouses and other light buildings. They are more common in commercial and some institutional buildings, where their unique architectural configuration is desired.

A cantilever support consists of a post or column supporting an anchor arm and a cantilever arm. The anchor arm is shorter and more massive, and balances the weight of the longer cantilever arm. In some cases, the mass of the column provides the counter balance to the cantilever. In other systems, a central column supports two opposing cantilever arms. To increase the distance between sup-

ports, a suspended arm may be placed between two cantilevers. Cantilever support systems may be composed of steel beams or trusses, reinforced concrete, or occasionally wood.

Dome

Domes are used primarily as architectural ornaments for public buildings, churches, terminals, etc. They provide a large open space with a high ceiling. The weight of the dome is transmitted evenly around its circumference.

A geodesic dome derives its strength from a geometric lattice of trusses. The pattern of triangles or polygons that comprise the lattice gives it a faceted appearance. This is distinct from the smooth surface of a regular dome.

Structure Types

Load Bearing Walls

Buildings with load bearing walls are substantial structures, composed of stone masonry, concrete or other materials capable of withstanding a compressive load. As the name implies, the weight of the structure is supported entirely by a series

Figure 2: The four basic types of building structures

of walls. The spans between the walls normally will not exceed 20 to 25 feet (< 10 meters). The size and shape of the interior rooms are limited by the arrangement of the bearing walls.

Stone:

Stone is not used frequently in modern buildings because of the high cost. However, its high compressive strength make it an excellent material for construction of larger structures. Classical architecture made extensive use of stone for palaces, churches, government and institutional buildings. The increasing cost of stone construction, and the development of less costly framed structures, is reflected by the low percentage of stone buildings in newer built-up areas. Modern use of stone is, in many places, restricted to government and institutional buildings where the desire to maintain traditional appearances outweighs the cost.

Figure 3: Multi-story, masonry building, bearing wall construction

The principal recognition factors for a load bearing structure built of stone are:

- The structure has a heavy, substantial, massive appearance.
- The walls in stone buildings are, by necessity, thick, causing windows and doors to be recessed. The width of the walls may also be observed if parapets are present on the roof.
- There are relatively few windows and doors. They are normally small, and frequently have arches at the top to maintain structural integrity.
- The color or tone will vary with the type of stone used. If larger blocks are used, the pattern of joints between the blocks may be visible. The surface may be smooth if cut stone is used, or rough if the blocks are of shaped stone.

Note: Framed structures are sometimes faced with stone. The thinner walls and abundance of windows and doors will help to distinguish these. Since stone is expensive, frequently only the front of the building would be faced.

Brick:

Brick, adobe, cement blocks and cinder blocks are man-made substitutes for stone and their collective use is referred to as masonry construction. (Stone construction is also included as a subcategory of masonry.) As such, they are much less expensive, and are frequently used in smaller buildings in areas where the raw materials are available and/or wood is not available. Construction methods are similar, but adobe is restricted geographically, while cement and cinder

blocks are used mainly for industrial or storage buildings, and some small commercial buildings. In addition, cement or cinder block walls are sometimes covered with a decorative facing, such as brick, artificial stone, plaster (stucco) or siding, particularly in small commercial buildings.

The way in which masonry (particularly brick) buildings are constructed gives these buildings a distinctive appearance. Load bearing walls can be distinguished from framed structures faced in brick by the use of these characteristics.

The principal recognition factors for a load bearing structure built of brick are:

- Load bearing walls are characterized by relatively small windows and doors with lintels or brick arches above them to maintain structural integrity.
- Because the walls provide the structural support, windows and doors cannot exceed more than one third of the wall, unless special measures are taken.
- Windows and doors must be aligned vertically to maintain structural integrity. The sections of wall between openings provides the load-bearing strength.
- Load bearing walls must be sufficiently thick to support the cumulative weight of the roof and upper stories. Therefore, the walls on the lower stories are thicker than the walls on the upper stories. Windows and doors are recessed in proportion to the thickness of the walls, with windows on the lower floors being recessed deeper. In some cases, additional glass is placed flush with the exterior of the wall, concealing the recessed interior window.
- Floor joists must be anchored in the side walls, particularly in larger structures, and anchor plates or wedges (often decorated) may be visible.
- Load bearing wall structures rarely exceed 6 stories in height.

Brick load bearing walls are used in all classes of buildings where a nearby source of bricks makes it economical. The increase in the use of concrete because of its strength, versatility and lower labor cost results in fewer new buildings made of brick. However, older brick structures are locally plentiful.

Concrete:

Concrete has high compressive strength, making it an excellent material for load bearing walls. In addition, it can be given substantial tensile strength through the addition of steel reinforcing rods. Thus it can be used for floors, ceilings, roofs, and as beams, as well as for walls. It is easily handled by machinery, reducing labor costs during construction.

Load bearing buildings made of concrete fall into three categories: poured-in-place, tilt-up, and box-wall. The first two are very similar in design, and vary only in the way they are assembled. In the first, forms are assembled where the floors, walls etc. are to be located, and the concrete is poured into the forms.

The concrete structure is formed in place. In tilt-up construction, the walls are laid in slabs on the ground and lifted or tilted into place. The tilt-up method requires a high level of technology, and is used where labor costs are expensive. In either case, the interior walls may be either load bearing or framed. These methods are rarely used in buildings taller than one or two stories, usually for storage buildings, industrial buildings and public buildings such as auditoriums and gymnasiums.

The principal recognition factors for a load bearing structure of poured-in-place or tilt-up construction are:

- They are low structures, usually one or two stories, but they may be 20 feet (6 meters) or more in height.
- There are few window and door openings, which are small. Most structures of this type require little natural light, but may use skylights (often "sawtooth") in the roof.
- The walls must be thick enough to support the weight of the structure. This is reflected by the recessed doors and windows.
- They are usually of a simple box shape. Construction costs are kept down by the simple design, appropriate for industrial and storage structures.
- Roofs will not be high pitched. Normally a low arch or horizontal truss support is used. Sawtooth skylights may be present.

Box-wall construction uses a framework of load bearing walls braced with concrete floor/ceilings, resulting in a structure composed of a series of boxes of uniform size and shape. This type of construction can be used for multi-story buildings, and is commonly used for apartment buildings and hotels. This is a relatively recent form and is found in newer developments.

The principal recognition factors for a load bearing structure built of box-wall construction are:

- The individual cells (boxes) that comprise the building structure can usually be identified from the exterior of the building. Only one wall of each cell, that which faces outward has windows.
- The walls are thick, resulting in recessed windows and doors, but less than on other load bearing walls because of the added support of the concrete floor/ceilings.
- The added support of the concrete floor/ceilings also allows the walls to maintain a constant thickness rather than being more massive on lower floors.

Figure 4: High-rise concrete building, box-wall construction

- There are few windows and doors, especially on end walls. End walls will often have only a single vertical row of windows to provide light to stairwells.
- The roof will normally be flat because of the box-wall construction.

Framed Construction

Framed construction consists of a rigid framework of supporting columns and beams (posts and lintels) over which the walls and roof are constructed. The framing can be composed of wood (for smaller structures) steel, concrete, or a combination. When the columns are made of one material and the beams or trusses of another, it is called a "composite framed structure." Large, multi-story apartment and office buildings, as well as single- and multi-story industrial buildings use reinforced concrete framing.

Framing allows for more flexibility in the layout of rooms. Larger rooms are possible, but columns may be present. Architecturally, framing allows for greater variety in building styles and appearance. The frame structure may be entirely covered, giving the building a more massive appearance (heavy clad), or large windows can be used for a more open appearance (light clad). Framed structures range from single story residential buildings to high-rise apartments, office buildings and skyscrapers.

Frame construction has developed from simple post and beam construction, evolving through several distinctive styles to the modern light clad skyscrapers. Yet all frame structures are based on the same basic framework, horizontal beams or lintels that support the roof and floors, and transmit the load to a series of columns or posts which provide the vertical support for the structure. The terms "post and beam" are commonly used in reference to wood structural members, while "column and lintel" refer to concrete, steel, trusses, and other advanced structural members.

Post and Beam Frames

Basic frame construction is well illustrated by the wood post and beam structures popular in northwestern Europe from the 12th through the mid-19th century. These buildings utilized heavy, fire-resistant timbers of great strength joined into box-like frames. The frame was set on a stone or brick foundation, and diagonal braces were commonly used. Since the frame supported the structural load, the walls could be made of lighter materials, such as boards, panels, mud and straw, stucco, a single layer of brick, or similar materials. In the orient, frame buildings with walls of light screens and paper are common. In newer buildings, these light, non-load bearing walls are referred to as curtain walls.

These older post and beam buildings were frequently partitioned on the inside to provide space for various functions, including retail, light fabrication (hand crafting), and residential areas within the same building.

In Germany and other parts of northwestern Europe, the heavy wooden timbers of the framing were often left exposed, with plaster, or other materials, filling in the spaces between the timbers. This highly decorative style is referred to as half-timbered construction. It is common for these buildings to have the upper floor overhang the lower by a foot or so. The overhang protects the lower area from weathering, and the cantilevered overhang counterbalances the load on the interior parts of the frame.

A modern development is the light wood frame construction referred to as "balloon type." This method, uses regularly spaced, light weight studs, rather than massive posts, nailed to light weight sills and joists. Sheathing of the interior and exterior walls adds rigidity to the structure. Thus a "load-bearing wall" is constructed out of a wooden frame, that is the frame is not structurally independent. Many small residential buildings in the United States utilize this type of construction, because the light weight members are much less expensive than heavy posts and beams. The exterior walls may be clad with wood, metal, vinyl or other siding materials, or may be faced with a thin layer of brick or stone.

Framed, Heavy Clad

When the use of structural frames was introduced in the 1890's, the frame structures were covered (clad) with a layer of brick or stone to give the building a more massive and substantial appearance. The ground floor was often faced with stone, while the upper floors were clad with bricks. This makes these early frame structures difficult to distinguish from load bearing structures.

The following characteristics can aid in the identification of framed, heavy-clad buildings:

- Most buildings taller than six stories are framed.
- Framed buildings have a higher proportion of windows, especially in office buildings. However hotels will have fewer windows, commonly one per room.
- The exterior walls have the same thickness on all floors, so the windows will not be recessed.
- The columns will often be visible at the ground floor. They can be seen to extend upward by noting the position of the windows, which are always between the columns.
- Older frame buildings were constructed along classical lines to give them a more massive appearance. The ground floor forms a heavy-looking base called the pediment. It has large windows, heavy columns and is usually faced with decorative stone. The main part of the building is the shaft, and has a uniform appearance. The top floor (the capitol) is a lesser version of the first. It may also have large windows and decorative columns.

In the 1920's and 1930's, framed buildings took on a more modern appearance, as architects tried to get away from the more traditional styles. There are specific characteristics that help to identify these buildings.

- Windows are more abundant, frequently filling all the wall space between columns.
- Curved windows are sometimes present, often using opaque glass bricks.
- Curved windows are placed at the corner of the structure, demonstrating that the structure is framed.
- The building is more uniform in design, the pediment, shaft and capitol divisions are eliminated.

Framed, heavy-clad structures proved to be ideal for manufacturing and storage. The lack of interior load-bearing walls, and the ability to maximize natural lighting through large windows are of particular importance. These structures are commonly used where large open rooms and lighting are important, such as manufacturing, warehousing and for parking garages.

The principal recognition factors for a framed, heavy-clad industrial-type structure are:

- A maximum proportion of the exterior walls are devoted to windows. Cladding covers only the columns and beams.
- The interior columns are massive, either reinforced concrete or heavy steel I-beams. These would be visible in a building under construction.
- There are large open bays in the interior of the building, allowing for the storage or manufacturing functions.
- Loading docks and large doors are present on the ground floor.
- These structures are low and broad in shape.
- There are usually ventilation devices, such as monitors, present on the roof.

Framed, Light Clad

In the early 1950's, the modern high rise skyscrapers began to appear. Since then, they have become abundant in the downtown areas of cities around the world. They maximize the utilization of space in the crowded downtown areas, as they can be built to great heights at a relatively low cost. They provide large interior areas for office space or apartments.

The structural framework is composed of steel, or a combination of steel and reinforced concrete. The exterior varies from large windows to a thin covering (curtain wall) usually metal, with few or no windows.

The principal recognition factors for a framed, light clad, high rise structure are:

- The style is almost always quite simple and without ornament.
- Pediment, shaft and capitol are not present.

Figure 5: Photograph of a framed, light-clad building under construction. Note the column supports and the rotating, tower-mounted construction cranes.

- The exterior walls are thin, especially in contrast to heavy clad and load bearing construction.
- Columns and beams are normally visible, especially on the ground floor and often through the windows.
- These buildings normally have a very high proportion of windows.
- This type of construction is used for tall buildings, four stories and taller.

Composite

A composite structure utilizes load bearing outer walls (masonry or concrete) with framed interior walls (wood, steel, concrete, or combination). These buildings are difficult to distinguish from load bearing wall structures. This type of construction is used for single-story and shorter multi-story buildings. When the building's function requires large, open interior areas (industrial or storage), it is probably a composite structure. Poured-in-place and tilt-up concrete buildings frequently utilize framed interior walls.

Stressed Skin

This type of construction is used only to provide support for relatively light roofs. All of the loading is carried by cohesion in a thin shell which comprises the roof. Stressed skin structures may be simple (curved or domed roofs) or composite (sawtooth roofs) but always have a curved surface which carries the loading. The curved surface does not show a distinct ridgeline, and shadows on the roof are gradational.

Stressed skin roofs are usually placed on frame structures. Occasionally, as with some domed structures, the stressed skin dome may rest directly on the foundation. The structural members may be steel or reinforced concrete, with a sheet metal skin.

Pneumatic

Pneumatic structures are inflatable buildings with distinctive rounded shape and "balloon-like" appearance. They are frequently used as temporary structures until permanent facilities are constructed, or where structures are needed for a short term only. They are made of cloth or plastic, and may have a light framework of aluminum.

Figure 6: A pneumatic building. Note the rounded corners and the special entrance structure.

Figure 7: Summary of building structural types

Roof Types

Flat Roofs

A flat roof is one that is pitched only enough to allow for drainage of rainwater. Buildings with flat roofs are often administrative or storage buildings within industrial areas, but the presence of monitors, vents, or chimneys indicates that some type of manufacturing or processing activity is taking place inside. Numerous air conditioning compressors indicate a high cooling demand, such as an electronics facility.

Flat roofs are often covered with asphalt or asphalt and gravel, but in larger structures may be of reinforced concrete. The flat roof will have an even tone across the entire surface, except for the shadows of roof-top structures.

Shed Roof

Shed roofs have only one sloping plane. They are used on structures of light construction, often attached to a larger structure. Buildings with shed roofs are used primarily for storage or vehicle maintenance. They are relatively small in size.

The shadow is a good indicator of a shed roof. Also, it will have an even tone over the whole surface. The roof can be covered with shingles, or by corrugated or sheet metal.

Gable Roof

A gable roof is composed of two planes sloping in opposite directions, and meeting at a pronounced ridgeline. The ridgeline is almost always parallel to the long axis of the building. They are common on residential and industrial structures. Buildings with gable roofs may be of frame, load bearing or combination construction.

On residential buildings the roof is covered with shingles or tiles, or more exotic materials in non-industrial countries. Shingle or metal roofs are found on industrial buildings, where this type of roof is an indication of load bearing walls.

The shadow is a good indicator of a gable roof. In addition, the pronounced, longitudinal ridgeline separates the two halves of the roof, with the sunward side being lighter in tone.

Sometimes on wider buildings, two parallel gables are placed on a building, giving the roof a characteristic "M" shape. The two ridge lines and alternating light and dark tones of the four roof surfaces make recognition easy.

Hipped Roof

A hipped roof slopes down on the sides and the ends, with the surfaces meeting at a ridgeline parallel to the long axis of the building. If the structure is square, the surfaces meet at a peak. Shingles or tiles are common roofing materials.

Hipped roofs are common on residential and institutional buildings, and are sometimes found on administrative or engineering buildings in industrial areas. Hipped roofs are primarily associated with buildings having load bearing walls.

The pronounced ridgeline and triangular ends identify a hipped roof. The four sloping surfaces will have slightly different tones depending on their orientation with respect to the sun.

Gambrel & Mansard Roofs

The terms gambrel and mansard are often used interchangeably, however there is a distinct difference. Both have their sloping sides divided into two sections, a shallow upper portion and a steeper lower section. Gambrel roofs are commonly used on barns, with the roof sloping in two directions. A mansard roof slopes in four directions, similar to a hipped roof. Metal, shingles and tiles are common roofing materials.

Gambrel roofs are used in buildings requiring high, clear spans, such as warehouses, and heavy industrial buildings with load bearing walls.

These types of roofs are distinguished by their shadow, and by the slightly different tone of the roof components.

Deck Roof

A deck roof consists of a flat upper surface, with sloping surfaces on two or four sides. Sometimes the sloping surfaces may be narrow and hard to detect.

Deck roofs can be distinguished by their shadow and the darker tone of the sloping surfaces facing away from the sun. They will never have parapets, unlike flat roofs.

Sawtooth Roof

A sawtooth roof is very distinctive, being composed of parallel rows of oppositely sloping surfaces. One set of surfaces has a more shallow slope and is covered with roofing material. This surface may be flat or curved (stressed skin construction). The opposite set of surfaces are steeper (sometimes vertical) and contain windows for light and ventilation. The orientation is such that maximum lighting is obtained through the windows. The buildings usually are of frame

Figure 8: Sawtooth roofs. A) Sawtooth roof with skylight and ventilation windows, common on industrial buildings. B) Stressed-skin roof on sawtooth pattern.

Figure 9: Diagrams of different roof types, showing vertical and oblique views, and typical shadows

construction, with steel trusses supporting the roof sections. The roof, and often the rest of the building, is constructed of metal.

Sawtooth roof buildings are most common at light manufacturing industries, such as textiles and aircraft. When located at a heavy manufacturing facility, they are on buildings housing machine shops, engineering or light assembly areas.

The "sawtooth" profile of the roof yields a distinctive shadow. In addition, the alternating, parallel lighted and shadowed surfaces create an easily recognized pattern.

Curved Roof

Curved roofs include arched or barrel-shaped structures as well as domes. These are usually of stressed skin construction, and almost invariably composed of metal, plastic or waterproofed cloth, though occasionally concrete is used.

Lightly curved roofs are commonly used on storage structures, as they allow for large, open interior spaces. Arched roofs are more utilitarian and are used for many purposes. Domes are used on stadiums and similar facilities, as well as superstructures on some government and religious buildings.

The curved surface of the roof is readily seen on the buildings shadow. There is no ridgeline, with the tone of the roof grading from light to dark across the curve.

Butterfly Roof

A butterfly roof is a cantilevered structure designed to provide overhead shelter. It consists of a single wall with two wing-like roofs projecting on opposite sides. These are commonly used as shelters in vehicle maintenance areas or storage and transshipment facilities.

Roof-top Structures

Monitors

A monitor is a raised portion of a roof with louvres or vents along the side to admit light and air. The term clerestory is also used to describe such structures, but implies a larger structure. Monitors can be either longitudinal (running parallel to the long axis of the building) or transverse (perpendicular to the long

Figure 10: Flat-roofed buildings with monitors

axis). They may be found on any type of roof where there is a need for light or ventilation.

Monitors are found mainly on industrial buildings, and can have various configurations, depending on the type of roof and the particular requirements of the building. Large monitors or clerestories indicate the presence of activities that produce a great deal of heat, such as smelting or metal forming.

The shadow that the monitor casts upon the roof of the building makes the location and identification of monitors relatively easy.

Figure 11: Gable-roofed buildings with monitors

Valley Roof

A valley roof is a V-shaped angle formed at the intersection of two inclined roof surfaces. This occurs on buildings that are composed of two or more sections, rather than a simple rectangle. It is found mainly on residential, institutional and administration buildings.

Dormers

A dormer is a small structure projecting from a slanting roof, usually housing a window or louvre. It usually indicates the presence of an extra floor under the roof. Some older industrial facilities have dormers on buildings where this space is used for administrative or living space. Dormers are normally restricted to residential and some older administrative buildings.

Figure 12: Dormers with various roof types

The shape and composition of the dormer will usually match that of the rest of the roof, and many styles are possible.

The shadow of the dormer is a distinctive identifier.

Parapets

A parapet is an outside wall that extends above the roofline, forming a low wall around the outside of a building. They are found almost exclusively on flat-roofed buildings.

The shadow of a parapet is its most distinguishing characteristic.

Firewalls

Firewalls are used to contain the damage from structural fires to a portion of a building. They are interior walls built of brick, concrete or other fire-resistant material. To keep the fire from spreading across the roof, firewalls are built up several feet above the surface of the roof. They may or may not be part of the structural support system of the building.

Figure 13: Building with a masonry firewall. These are common on buildings such as motels, multi-family dwellings and multi-unit commercial buildings, such as those at strip shopping areas.

Firewalls can be associated with any type of roof. They are commonly found on storage buildings and warehouses, some light manufacturing facilities, and in residential, commercial and office buildings.

Where they are present, firewalls are usually equally spaced along the building. The shadow cast by the extension of the firewall above the roof is distinctive.

Other Structures

In taller buildings, a small, rectangular structure housing the elevator machinery can be seen on the roof, especially on flat roofed buildings.

Various types of air conditioning units can be found on rooftops. These can range from small to medium sized compressors or radiator coolers to large evaporative

Figure 14: Flat-roofed building with parapet and tower superstructure

Figure 15: A flat-roofed building with a cupola superstructure. Cupolas may contain a helioly or serve as a covering for a high, circular room.

Figure 16: A gambrel-roofed building with a steeple superstructure

systems. Cooling units are partially or wholly composed of metal, and give a building a distinct radar signature. The size and number of coolers can be used to judge the cooling requirements of the facility located within the building, and can help identify its function. Electronic equipment generate a great deal of heat and need a cool clean environment to function, thus a large number of coolers is an indicator of an electronics facility.

Ventilators are abundant on buildings housing chemical processing. Smokestacks provide a vent for products of combustion, from the buildings heating system, or from boilers associated with processing activities.

Geographic Variations

Building styles and construction materials vary depending on the availability of materials, the local climate and cultural differences. These differences are most evident in rural areas, small towns and suburban parts of larger cities. The central parts of major cities tend to be similar worldwide, especially where there has been substantial new construction of high rise buildings.

Areas with high precipitation, especially snow, will have very few buildings with flat roofs. High pitched roofs are common in areas with greater snowfall. Flat roofs, conversely, are preferred in dry climates. The availability of materials is also dependant on climate.

Local variations are discussed in more detail in Section 6, Cultural Areas, but a brief summary of climatic areas and the locally available construction materials is given below:

Temperate areas:

- Moderate to heavy precipitation.
- Considerable temperature variation between seasons.
- Local building materials: wood, brick, stone and concrete.

Tropical areas:

- Heavy precipitation.
- Warm, slight variation between seasons.
- Local building materials: wood.

Highland areas:

- Very heavy precipitation, except in rain shadows.
- Moderate to slight temperature variations.
- Local building materials: stone brick and some wood.

Desert or steppe areas:

- Light precipitation, arid to semi-arid.
- Wide temperature variations.
- Local building materials: stone, brick and some concrete.

Mediterranean areas:

- Moderate precipitation (seasonal).
- Moderate temperature variation.
- Local building materials: stone, brick, concrete and some wood.

Polar areas:

- Light precipitation.
- Cold, great temperature variation.
- Local building materials: stone and some wood locally.

CHAPTER 3 – TRANSPORTATION

General

Contents

This section covers all aspects of transportation (ground, air and maritime), including routes, terminals, transshipment facilities and their associated structures. The section on Airfields includes the information needed for portrayal on cartographic products. An in depth explanation of airfields, facilities and navigational aids is given in Module 6, Aeronautical Data Maintenance, which is designed for the Aeronautical Information Specialist. Pipelines are included in this section as they are a means of transporting materials over long distances.

Although power distribution networks and communications networks are also lines of communication and share basic characteristics with these transportation systems, they have enough unique characteristics to warrant inclusion elsewhere. Power lines are discussed along with power generation facilities in Chapter 4 of this module. Communications facilities, both wire and wireless, are described in Chapter 5.

Lines of Communication

As mentioned above, transportation facilities fall into the broader category of Lines of Communication (LOC's). They are concerned with the movement of some commodity (people, materials, electrical power or information) from one point to another. As such they have several features in common.

Each LOC is composed of a network with definite starting and ending points, or terminals. The nature of the terminals is characteristic to that particular form of transportation or communication. For instance, railroad terminals are distinctly different from ports, and the nature of a radio communications installation can often be deduced from the configuration of the antennas. The terminals may be localized, such as railroad stations, ports and radio transmitters, or they may be dispersed as in warehouses receiving goods by truck, electrical customers, or the garage you park your car in.

The network connecting the terminals is also different for each system. Different "vehicles" are used in each system (ships, railroad cars, trucks, pipelines or radio waves) and each has different requirements for the route it must follow. Ships require navigable waterways, trains require tracks, trucks require roads, and radio requires a suitable geometry between transmitter and receiver. Some, like ships and trains, have a limited number of legs in their network, others, like roads and telephone lines, have a greater degree of interconnection, while others, like radio have few restrictions.

Often, the commodity may have to utilize more than one system to reach its final destination. For instance, hardwoods harvested in Southeast Asia are shipped by railroad to the coast, where they are loaded on ships for transport to the U.S. Upon arrival at the destination port, they are loaded on trucks for delivery to the distributors. At each place where the materials change from one transportation system to another, a transshipment facility is present, with specialized equipment for on-loading, off-loading, metering and storage of materials.

Transportation Systems

Transportation systems differ from the other LOC's (communication and power transmission), in that they deal with physical commodities, and that they normally require some type of storage facility for the commodity, as well as facilities for the transporting vehicles, and that they frequently connect with each other through transshipment facilities.

The various systems are fairly easy to distinguish on large scale imagery, but distinctions become more difficult at smaller scales. There are, however, certain characteristics that will help to identify them. The nature of the routes, terminals or associated features are often distinctive.

Roads

All of us use roads daily, often with little thought as to how the roads we travel on would look from the air. The large number of roads, in comparison to other types of transportation routes, their high degree of interconnectedness, and the mobility of wheeled vehicles make highway transportation extremely versatile. The relatively low capacity of individual vehicles, however, make highway transportation more expensive than those systems which can carry larger quantities of materials.

Roads are wider than the vehicles which use them, and frequently are two or more lanes wide. The small turning radius of wheeled vehicles make sharp turnouts, curves and branchings possible. Road networks are more extensive, with many intersections. Steeper grades (in excess of 7%) are possible. On major highways, the straight alignment, gentle curves and grades may resemble those of a railroad, but the greater width and presence of intersections are characteristic. Bridges usually maintain the width of the roadway. Terminal facilities are small and dispersed, and may have large paved or graveled parking areas, often rectangular in shape.

Railroads

Railroads are the second type of overland transportation systems. Trains, however, are restricted to the relatively few sets of tracks present in any given area. Their ability to handle large quantities of materials and travel at high speeds make them much more economical for hauling materials for long distances.

Trains travel on sets of tracks that are spaced less than the width of the cars. The ballast supporting the tracks forms a strip of comparable width to a single lane road, but single-lane roads rarely maintain the alignment and gentle curves and grades of a railroad. Cuts and fills are abundant, maintaining grades below a maximum of 6%. Tracks intersect and diverge tangentially. Bridges are just wide enough to accommodate the tracks, and, in some cases, do not have a solid flooring, making them appear even narrower. Terminals are in the form of railroad yards, which can be quite extensive, or isolated facilities at the ends of spurs or sidings that diverge from the main track.

Bridges and associated features

As overland transportation systems, both roads and railroads must deal with the many obstacles present on the land's surface. Since both must provide a smooth and relatively level surface for vehicles to travel on, the structures used to cross obstacles are very similar. Bridges, culverts, cuts, fills, tunnels, etc., differ very little between roads and railroads.

Airfields

Air transport differs from other systems as aircraft do not require a prepared route to travel upon. The primary features associated with air transport are the airfields. The runways, taxiways and navigation aides, are the only physical facilities involved in the actual transportation function. The rest of the airfield components can be considered as transshipment facilities. Air transportation is fast, but delivers directly to a relatively few destinations. It is also the most expensive means of transportation, and is used where speed of delivery offsets the higher cost.

Major airfields are readily identified by the pattern of the runways and taxiways, and the presence of parking aprons, hangars and aircraft. They are also somewhat isolated from the road network. Minor airfields, particularly those with dirt or grass runways, can be more difficult to detect, but are not easily confused with other systems. In some areas, specially widened and reinforced segments of roads are used as runways.

Waterways

Inland waterways and transoceanic routes have several differences. Inland waterways, like railroads, have a few set routes (rivers and canals) and are limited in the size of the vehicles they can accommodate. Terminals on inland waterways, therefore, tend to be small. Maritime transportation is relatively slow, but because of its ability to handle large volumes of cargo, it is perhaps the most economical.

Waterways may be natural or artificial. Natural waterways will curve in an irregular fashion and will vary in width. Canals will be straight or gently curving and maintain a constant width, with occasional turning basins present. Both types are

substantially wider than roads or railroads, and will have varying tones on the surface due to different sun angles and water depth. In addition, the water surface will always be below the surrounding ground. Small dams, with associated locks, are often used to maintain the water depth required for navigation. Terminals on inland waterways are often small and may be dispersed along their length. Transoceanic shipping can utilize very large vessels carrying large amounts of cargo, so coastal port facilities are often large and complex.

Pipelines

Pipelines are unique in that the material is carried directly through the pipeline, rather than in a vehicle. This means that very little human supervision is needed. Transportation is not affected by the weather, as are other systems. Liquids and gases are the only materials that can be moved via pipelines, but some solids (such as coal) are pulverized and mixed with water to form a slurry. The volume of material that can be moved depends only on the diameter of the pipe and the strength of the pumps. Although limited in extent, pipelines are very economical for long distance transportation, and are used extensively in urban areas for distribution of natural gas, and water, and for disposal of wastes.

Pipelines on the ground surface are readily recognizable. They are straight and narrow, and make angular bends. Frequent 90° bends at expansion joints are visible. Junctions and branchings are rare, except in oil fields. Underground pipelines can be very difficult to locate. A scar may be visible on the surface of the ground, and when passing through forested areas, a cleared way often reveals the route of the pipeline. In other areas, particularly urban areas, there may be no surface expression of a pipeline. Terminal facilities are composed of pump stations, storage tanks and processing facilities which are readily identified.

Roads

Introduction

A road is a long, narrow stretch of ground, usually graded, often paved, used primarily for the movement of wheeled vehicles. Roads are classified on the basis of their surface type, their ability to handle large volumes of traffic and heavier vehicles (trafficability), their ability to handle traffic in adverse weather (weatherability), and the amount of traffic they can handle (width or number of lanes). Footpaths and trails are included here, even though they are not intended for wheeled vehicles.

Road improvements (grading and paving) are done for three purposes, to smooth the surface allowing vehicles to travel faster, to improve trafficability and to improve weatherability.

Grading evens out the surface, and gives it a slightly convex shape (crown) which allows rain water to drain off the road surface. In addition, small ditches

are usually scraped out parallel to the road to carry the water away. Keeping the water away from the road surface helps to preserve the surface and prevent damage during periods of wet weather.

Paving provides water-proofing and improves the load bearing capacity of the road. Pavement consists of rigid surfaces such as concrete, stone paving blocks (Sett) or brick, or flexible surfaces such as asphalt (bituminous surface). Rigid surfaces spread the load more effectively than flexible surfaces, and are used where a large volume of traffic, or heavy vehicles are expected. Expedient surfaces, such as logs or pierced metal planks, are sometimes used to make rapid improvements to roads, often in support of military operations.

Road Construction

The weight of a vehicle is transferred to the ground in the relatively small area where the tires (wheels or tracks) touch the ground. This means that the road surface must be able to withstand heavy loads placed on a small area. In order to do so, the road must be constructed so as to distribute this load over a larger area.

The central part of the roadway, the traveled way, is the portion designed to carry the traffic, and is of more substantial construction than the adjacent shoulders, which are meant only for emergency parking. Between the shoulders and the lateral drainage ditch, there may be an area of unsurfaced fill material.

The graded surface can be compacted to improve its load bearing capacity. Compaction helps keep the soil from being pushed out from under the wheels. If further improvements are to be made, this compacted soil forms the subgrade or foundation for the road. When the natural surface is of poor quality material, or when the road must be built up to provide for drainage, additional material, usually some mixture of earth and stone is brought in for use as the subgrade.

To help spread the load from the vehicles' tires, a layer of well-graded aggregate (gravel or other granular material) is placed on the subgrade and compacted. This layer is known as the base course if it serves as a foundation for a solid pavement. When this aggregate forms the surface of the road, it is sometimes called a "metaled" road. The aggregate may also be mixed with a binder, such as bitumen, clay, etc., to help shed water and keep down dust.

A pavement is applied to the road surface to maximize weatherability and trafficability. It keeps the water away from the base course and subbase, so the road's ability to handle traffic is not reduced during wet weather. It also helps to distribute the load more effectively, giving the roadway greater strength.

Rigid pavements are used on roads designed to carry heavy vehicles or large volumes of traffic. The rigid surface is very effective in spreading the load from heavy vehicles over a broad area. Major highways are almost always constructed with a concrete surface. Stone paving block or brick surfaces are still found on some old roads, but rising labor costs make these materials uneconomical in most areas. In some places, they have been covered over with a layer of asphalt.

Figure 1: Diagram showing the components of a road's surface. Depending on the surface type and construction methods, the boundary between the travelled way and the shoulder may be difficult to detect.

Asphalt is less expensive and is preferred for lesser highways and feeder roads. Since it is flexible, especially when warmed by sunshine in the summer months, a substantial base course is needed if heavy traffic is expected. For bituminous-surfaced roads, the base course provides most of the load bearing strength, while the pavement serves mainly as water-proofing. A bituminous surface placed over a graded subbase has low load-bearing capacity, and is referred to as a "light-surfaced" road.

Drainage

In order to support traffic in all kinds of weather, the roadway must be kept clear of water. The first improvement made on a roadway, grading, promotes the drainage of water from the road surface by making the center of the roadway higher (crowning), and helps keep it away from the road via lateral drainage ditches. Further improvements to drainage consist of enhancing the lateral drainage ditches, building-up the road in low-lying areas, providing a path for water to flow under the road via culverts or bridges, and water-proofing the road surface.

Alignment

Alignment is the process of making a roadway straighter, with smooth, wide curves and gentle grades. This enables traffic to move at a higher rate of speed and eliminates traffic bottlenecks. Within a given area, higher classes of roads will have better alignment than roads of lower classification. Major highways will exhibit the same characteristics as railroads, but can be distinguished by their greater width, the presence of interchanges, and the lane markings will be visible at larger scales.

Road Classification

Roads are classified on the basis of their ability to handle increasing volumes of traffic, increasing sizes of vehicles, and their ability to remain serviceable in adverse weather conditions. These capabilities are widely variable, and depend on the type of road surface and method of construction, road width, alignment, drainage, terrain and climate.

Under set conditions of terrain and climate, the classification of a road is proportional to the improvements that have been made to the roadway. For instance, in an area of hilly terrain that receives substantial amounts of rainfall, only those roads with good drainage and pavement over a compacted base course can be considered as all-weather roads. In areas of level terrain and low precipitation, particularly where gravel soils predominate, a road can be classified as all-weather without improvements beyond basic grading and drainage accommodations. This has the unfortunate corollary that the photo identification factors for road classification are not constant throughout the world, particularly for loose-surface roads.

Due to variations in road construction, road condition, terrain and climate, gradations exist between road classes. This can make the determination of the proper classification difficult at times. It is important for the cartographer to be aware of all the factors affecting road classification in a particular geographic location. Ancillary sources should be consulted for information about road construction techniques and materials and climatic conditions.

Trails and Footpaths

Any route which is not wide enough to accommodate a four-wheeled vehicle (less than 1.5 meters wide) is classified as a trail. The common usage of this term describes a narrow traveled way with a natural, unimproved surface. There may be a few local improvements to carry the trail through difficult areas, such as side cuts on steep hillsides, and wooden plank paths over marshy areas.

The trail will appear as a single, narrow line, usually lighter in tone than the surrounding ground surface. Heavily traveled paths will be continuous with fairly sharp margins, but less traveled paths may appear discontinuous and have indistinct margins. Trails follow the line of least resistance, and will have an irregular trace even on level terrain. Short detours around obstacles such as rocks, wet areas and clumps of brush are common. On steep slopes, the trail will often zig-zag up the hill side with angular bends.

Trails are found in undeveloped areas, where materials are moved by

Figure 2: Trail

people or pack animals. Generally, there will be little agriculture and no industry present, however, in some undeveloped countries, large agricultural areas exist with few roads larger than trails.

In more developed regions, particularly in urban parks and suburban areas, foot paths and bicycle paths have been constructed. These may range from gravel-surfaced paths to paved surfaces with culverts and bridges and may even have stairways constructed up steeper hills. In larger parks and natural areas, hiking trails with varying degrees of improvements are also common. Less improved paths will resemble rural trails, while others may be quite distinct with sharp edges and constant width. If paved with asphalt, they may appear darker than the adjacent ground. Their common denominator is their narrow width, and for cartographic purposes they are classified as trails.

Tracks

Tracks are similar in most aspects to trails. The main difference is that tracks are wide enough to accommodate at least small four-wheeled vehicles (> 1.5 meters). A track is simply an unimproved traveled way on the natural ground surface. There are few improvements, except locally where needed to cross obstacles that cannot be bypassed.

Tracks appear as a pair of parallel lines where the vehicles' wheels have disturbed the ground and vegetation. They are usually lighter than the surrounding area, except in wet areas. In the winter, on snow-covered terrain, tracks will appear as parallel dark lines. On hard ground, bare of vegetation, tracks may not be visible. Tracks follow the line of least resistance, detouring around most obstacles, and will be straight only in areas of flat, firm ground.

Figure 3: Track

For cartographic purposes, description of a feature as a track implies repeated usage. Tracks serve as part of the road network, connecting with villages, farms, waterholes or other tracks and roads. While driving a vehicle across soft, undisturbed ground will leave marks, this does not make it a track. The intricate network of vehicle tracks around construction sites and military maneuver areas do not constitute part of a road network, and should not be designated as tracks.

Tracks are found in undeveloped areas where infrequent use does not justify the expense of road improvements. Tracks are also common between fields in agricultural areas, where they are used for movement of farm equipment.

The width of the track is an indication of the size of the vehicles traveling there. Cars and small trucks will leave tracks 1.5 to 2 meters wide, while tanks leave tracks from 3 to 4 meters wide.

Transportation

Cultural Features 29

Loose Surface, Fair Weather Roads

Loose surface, fair weather roads are characterized by a limited amount of improvement to the roadway. Normally this is limited to grading the surface. Locally in areas of soft ground, some gravel or binder may be added to the roadway. On steep slopes, small side hill cuts may be present, and cuts and fills are limited to sharp breaks in slope. Where tracks follow the line of least resistance along the surface of the ground, these roads have some improvement in their alignment, making the route a little straighter with more regular curves. Because of the lack of provisions for drainage, and the natural earth surface, these roads quickly become impassable in wet weather.

These roads appear as a continuous strip, lighter in tone than surrounding areas, with an irregular edge. Locally, wet areas will have a darker tone. The width is relatively consistent, but the roadway may be wider where vehicles try to avoid bad spots in the road. Continued use in wet weather may form paired ruts in the roadway.

Figure 4: Single-lane, fair weather, loose surface road

Fair weather roads are distinguished from tracks by their more even appearance, the lack of a dark strip down the center, and slightly better alignment. They are distinguished from all weather roads by the lack of drainage ditches and culverts, the irregular edges with no shoulders, blotchy appearance due to wet spots, and the lack of cuts and fills. If used during wet weather, they will be rutted and irregular.

Loose Surface, All Weather Roads

Loose surface, all weather roads are characterized by extensive improvements. Alignment is good, with regular curves. Cuts and fills help to provide a more even grade. The surface is graded and crowned, and consists of some combination of rock, gravel sand and/or clay that is locally available. It may be treated with chemicals or oil to serve as a binder and to control dust. Extensive provisions for drainage help keep these roads passable to at least moderate levels of traffic in wet weather.

These roads appear as a distinct strip, much lighter than the surrounding ground, with sharp but sometimes irregular edges. Often, there will be a slightly darker band along each side of the roadway, between the traveled way and drainage ditches. Shoulders are present, but the margins of the traveled way are indistinct. The unpaved surface may display an uneven texture. The road will have prominent drainage ditches and culverts. The width of traveled way and shoulders will be uniform, but the road may appear wider where fills are present.

Photo Interpretation Training Course

Figure 5: *Loose surface road and light surface road*

All weather roads are distinguished from fair weather roads by the presence of drainage ditches and culverts, the improved alignment, and the use of cuts and fills to keep an even grade. They are distinguished from paved (hard surface) roads by their very light tone, uneven texture, lack of distinct edges on the traveled way, and lack of center lines. Oil, bitumen or chemicals may be mixed with or sprayed on the surface material. This can give the roadway a distinctly darker tone, but the irregular edges and lack of centerlines reveal that it is a loose surface road.

Hard Surface Roads

In addition to the improvements listed for all weather roads, hard surface roads have a waterproof pavement which improves the weatherability and load bearing capacity of the road. Hard surface roads include a broad spectrum of roads, from narrow, light surface roads through divided superhighways.

Light Surface Roads

Light surface roads are built in areas where only light traffic is expected. They may form the primary road network in poorly developed areas, or they may serve as feeder roads in rural areas. They are narrow, rarely exceeding two lanes, and often only one lane wide. Because of the anticipated light traffic, improvements are kept to a minimum. These roads will quickly break down under heavy traffic.

The alignment tends to follow the terrain, with few cuts and fills, and steeper grades present in hilly areas. The pavement is also of an inexpensive type, hot oil or bitumen mixed with gravel, or a layer of asphalt over a light base course, often stabilized soil. Bituminous mix-in-place and "tar-mac" surfaces fall in this category.

Light surface roads are distinguished from loose surface roads by the darker tone of the bituminous or asphalt surface material, which contrasts sharply with the lighter shoulders. Lane markings are generally not present, in contrast to heavier surfaced paved roads of narrow width, and the edge of the paving may be irregular rather than straight.

Hard Surface Roads

Built to support heavy traffic during all types of weather, these roads have a prepared subbase and compacted base course supporting an asphalt, concrete or occasionally cut stone or brick pavement. The base course extends beyond the traveled way to form the shoulders. In the absence of divided highways, hard surface roads form the main road network, elsewhere they form a secondary network supporting a system of divided highways. They are most abundant in developed and industrial areas, and form at least the main streets in urban areas.

The importance of a hard surface road can be judged by its degree of alignment. Minor roads will follow the ground surface and have few cuts and fills. Major highways will be straight with wide, regular curves, and cuts and fills as needed to maintain an even grade. The width is proportional to the expected volume of traffic, usually two to four lanes, but occasionally wider, especially around urban areas. Drainage is well developed, and in hilly areas supplementary diversion ditches may be present.

Hard surface roads are distinguished by their even tone, constant width, sharp margins, well-developed shoulders and drainage, and by the lane markings that will almost always be present. The shoulders may be paved, in which case a solid painted line may mark the edge of the traveled way. Asphalt surfaces are most common, but concrete may be used in areas where heavier traffic is expected, especially around industrial facilities, ports, airfields and rail yards. Locally, particularly around older cities, cut stone (sett) or brick pavements may be used. These areas are rapidly being replaced or paved over with asphalt.

Figure 6: All weather, hard surface road on a fill. Cuts and fills allow the road to maintain a straighter alignment and more even grade.

Figure 7: A multiple-lane road (four lanes). Such roads are almost without exception hard-surfaced.

Urban Streets

Urban areas contain the greatest concentration of paved roads. In highly developed areas, all urban streets will be paved, while cities in less developed or agricultural areas may have only the main routes paved. The width and development of key roads indicates the location of major through routes, and can point to significant governmental, industrial, military or institutional facilities.

Urban streets differ from roads in rural areas. In built-up areas, shoulders are not common, instead the traveled way is bounded by curbing. In many cases, the road is widened to provide space for vehicle parking. Drainage is provided by underground piping with storm drains placed along the curbs. Sidewalks are commonly present on one or both sides of the road. This configuration is easily distinguished from less developed urban areas, where the unpaved streets lack the sharp, straight edges of paved streets.

In the older, central portions of some cities, the close spacing of the buildings restricts the width of the roads, sometimes as narrow as one lane. Many urban areas, particularly in Europe and the Far East, provide separate bicycle lanes, usually adjacent to the curb, but sometimes as separate paths away from the road.

Divided Highways

A divided highway is a hard surface road where the lanes of opposing traffic are separated by a physical divider or median, and where access to the road is limited to specially built interchanges. The divider is normally a strip of grass-covered ground of varying width, but in areas where road width is restricted, there may only be a concrete or steel barrier separating the lanes. There will be at least two, often more, lanes on each side of the median. Bridges, overpasses and underpasses are common where the highway crosses other roads or railroads.

Figure 8: A four lane divided highway, without a median

Alignment is very well developed, and all curves are broad and even. Steep grades are avoided through the extensive use of cuts and fills. Drainage is provided by a well-developed system of ditches and culverts. Within a country, the lane width will be constant, somewhere between 3 and 3.5 meters. The shoulders are usually the width of a traffic lane, and are strengthened to support the weight of parked or disabled vehicles. The shoulders may be of a different tone than the traveled way, and/or marked off with a solid line. A heavy base course, up to two or three feet thick, underlies the pavement and shoulders. The surface is normally concrete, but in some areas asphaltic surfaces are used.

Interchanges are designed to provide access to and egress from the highway with minimal impact on traffic flow. Configurations vary greatly, depending on the situation at the particular intersection.

Figure 9: Nine of the most common varieties of highway interchanges

Divided highways are readily identified, even on smaller scale imagery, because of their broad width, smooth alignment, characteristic interchanges and the presence of a median strip. The cleared ground on either side of the highway and on the median, along with the road itself cut a distinctive swath across the landscape.

Elevated Roads

In some areas, the road must be elevated above the surface of the ground. This is normally accomplished by placing the road on an earthen fill. In other cases, the road is supported on a long, bridge-like structure with a series of evenly-spaced supports. These elevated roads are always hard-surfaced, usually concrete. The shadow of the roadway and supports is usually visible and identifies the elevated road. The height of the road above the ground, the lack of a fill, and the fact that other roads pass freely underneath, are also keys to identification. This type of structure is sometimes referred to as a viaduct.

Figure 10: An elevated road

Identification of Pavement Types

Asphalt surfaces have a very dark tone when new, but appear lighter as the surface becomes older. Concrete is very light when new, but gradually becomes darker. Concrete surfaces are composed of rectangular slabs separated by expansion joints. The pattern of expansion joints is often visible on large scale imagery, and can be used to discern darkened concrete from light asphalt. Patched areas on concrete will show up as light, rectangular areas with straight edges. On asphalt, smaller patches are rounded, while larger areas are repaired by laying a new strip of asphalt. The new asphalt will be distinctly darker.

Concrete pavements can be distinguished from gravel surfaces by their even tone, straight, sharp edges that contrast with the shoulders, lane markings, and

Figure 11: A comparison of concrete and asphalt surfaced roads

the pattern of expansion joints. Heavy asphalt pavements have straight, distinct edges, as opposed to the irregular margins of light bituminous, bituminous mix and oil sprayed surfaces.

Cut stone pavements will vary in tone depending on the color of the rock used, but it will be somewhat darker than concrete. At very large scales, the texture of the blocks may be visible. Lane markings are indistinct or absent. The lack of expansion joints distinguish stone from concrete, but it may be difficult to discern between stone and asphalt. Brick roads, similarly, are of a dark tone, and at large scales, the pattern or texture of the bricks may be visible. Both pavement types are confined to older roads that have not been replaced or paved over. They are found in older urban areas, and rural areas in less developed countries.

Miscellaneous Roads

Several unusual solutions have been developed for roads through difficult areas such as swamps and areas of soft or intermittently wet ground. These are used when limitations of cost or time preclude the construction of a proper all weather road. These "expedient" road surfaces are often used to support military operations in undeveloped areas.

The use of logs placed across the roadway, forming a "corduroy" surface, dates back to before the advent of motorized vehicles. Log or wood plank surfaces are used to carry roads through swampy or wet areas, and are sometimes used to provide traction on steeper slopes of unimproved roads. They have been used in areas like northern Russia where the ground becomes very wet and soft during the spring and summer, but is frozen and firm in winter. A light surface "fascine" road is made by substituting bundles of sticks for logs. This provides only temporary passage for light vehicles. Corduroy and plank roads will appear distinctly lighter than the surrounding ground, and will contrast with the unimproved roads they connect to.

An expedient variation is to lay planks or logs in two parallel strips (or treads) to support the wheels of the vehicles. Another type of tread road uses stone, or sometimes concrete to provide support for the vehicles' wheels. This is less expensive and quicker than paving a continuous surface, but provides one-way travel only and requires specially constructed turnoffs for passing. The parallel strips of the treadways will be apparent at medium scales, and may resemble a railroad track, however the poorer alignment and lack of cuts and fills will distinguish them on closer examination. Wood tread roads are more common in northern areas such as Russia, while stone tread roads are more common in central Asia.

Pierced steel or aluminum planking roadways have been used in tropical areas. They can be constructed quickly and provide a firm traveled way for heavy vehicles. Their sharp, straight edges and high reflectivity are distinctive. The metal surface may reflect light toward or away from the sensor, and these roads may have a different tone on each half of a stereopair, similar to water.

Winter only roads cross areas of marsh, swamp or open water that freeze sufficiently to support vehicular traffic. Their location is marked by vehicle tracks on winter imagery. Unless you are able to identify an area as marsh or open water, the seasonal nature of these roads is not apparent. On imagery taken during warmer seasons, the location of these roads is not visible.

Associated Features

Most features associated with roads, such as bridges, culverts and cuts and fills, are common to both roads and railroads, and will be discussed in subsequent sections. The following features are unique to roads.

Fords

Most water crossings are via bridges, ferries, causeways, or fills with culverts. The superior mobility of wheeled (or tracked) vehicles, however, allows them to cross rivers or streams where an appropriate approach is available, the water is shallow, the current is slow and the bottom is firm. A ford is any location along a river or stream where the physical conditions allow vehicles or personnel to cross. It is normally associated with a road, track or trail. A ford is used where the low volume of traffic and/or high cost of construction do not justify building an improved crossing.

Fords are classified according to their crossing potential for foot traffic, wheeled or tracked vehicles. Fords along roads, tracks or trails are usually improved to allow passage of vehicles. Fords are also used as bypasses at bridges damaged or under construction. Potential fording sites are particularly important along rivers or streams characterized by high, steep banks and/or dense vegetation along one or both banks, as crossing sites for military operations.

Classification of fords for cartographic purposes may vary for different products. When describing a ford for a particular product, be sure to verify the usage of terms with the product specifications.

Fords are found within shallow reaches of rivers and streams. The bottom of the river must be firm enough to support traffic and free from protruding rocks and boulders. In streams with soft bottom materials, rock is added to make it firmer. Rock can also be placed along the ford to raise the bottom, making the water shallow enough to cross. Concrete surfacing, layers of sandbags, metal screening or matting, timber or wooden planking may also be used to improve trafficability.

The current must be slow to moderate (less than 1.5 meters per second). Faster currents can wash away vehicles, erode the bottom or carry large debris which can damage vehicles. The maximum water depth will vary with the type of vehicles using the ford. Permissible depths range from 0.5 meter for smaller wheeled vehicles, to 4.3 meters for tanks with fording kits. Climatic conditions, such as seasonal floods, droughts, freezing and other extremes of weather materially affect the fordability of a stream.

Rapids, white water and exposed rocks or boulders indicate a rocky bottom. Bars, braiding, and steep banks often indicate coarse-grained materials such as sand or gravel. Meanders and oxbows indicate relatively slow-moving water with fine-grained bottom materials. Angular drainage patterns with frequent sharp changes in direction indicate bedrock control of drainage and a rocky bottom. In swift-flowing streams in mountainous area, fine materials do not settle; therefore, the bottoms are rocky or firm.

The banks must be gently sloping and free of vegetation. Approaches to on-route ford are often graded and cleared, and rock may be added to areas with soft bank materials. Occasionally, approaches may be paved with concrete or bituminous surface material. Off-route fords must have the vegetation cleared away from the banks to allow passage of vehicles. Natural banks greater than 1 meter in height and with slopes greater than 60% are impassable for most vehicles.

A ford extends straight across the river or stream, connecting the approaches. Fords are often only one lane (2.5 to 5.0 meters) wide, but they can be much

Figure 12: A ford

wider (50 to more than 100 meters) depending on the traffic and local conditions. When determining the width of a ford, look for indications that the roadway continues across the channel. Sometimes there is a change in tone where the shallow depth and coarse bottom materials create a disturbance on the water surface, or where the bottom materials have been disturbed. Sometimes, faint lines may mark the edge of the traveled way. In some cases, the edges of the ford are marked by boulders or posts that protrude above the surface of the water, and may be visible on imagery. Where material is added to the river bottom to raise the level of the ford, the sides may appear as lines of ripples or eddies of a lighter tone than the surrounding water. Even where the actual course of the ford is not visible through the surface of the water, the presence of conspicuous roads leading to opposite banks of a river and the lack of a bridge or ferry indicate that the location is probably a ford.

During periods of high water, low water bridges can be easily confused with paved fords, as both are completely submerged. These bridges consist of concrete decking set on supports at a level which keeps the deck above water during the drier parts of the year. They are contained wholly within ravines and gullies. It is important to distinguish between low water bridges and fords because of differences in their load limitations.

Prepared Float Bridge Sites

Bearing a close resemblance to fords, a prepared float bridge site has roads leading to a prepared ramp into the river. However, at these locations, the depth of the water precludes fording. These sites are built mostly for tactical military uses, as backups to provide vital river crossings in case bridges are destroyed by enemy activity. They are found in areas where military conflicts are, or were, anticipated, such as in Germany and Korea.

Drop Gates

In some countries, such as South Korea, the fear of military invasion by a neighboring country has prompted the construction of obstacles that can be quickly dropped into place, blocking roads and highways leading into the country. They are placed at critical points along the road where the adjacent terrain is too steep to allow vehicles to leave the road to bypass the obstacle. These obstacles are collectively known as drop gates. They can take many forms, but there are two basic types, the overhead drop and the side drop.

A common form of overhead drop is a large, rectangular block of concrete, set on piers over the road. It is similar in appearance to an overpass constructed across the road, except that it does not support a road or other transportation feature. Explosive charges are placed in the piers. In the event of an invasion, the explosives are detonated and the block drops onto the road.

A side drop obstacle can be a rectangular or triangular block of concrete set upright on the side of the road. Explosive charges at the base tip the block so

that it falls across the road. Another type of side drop is made by placing a large number of logs or boulders on the uphill side of the road, behind a retaining structure. The explosives would break the retaining structure, allowing the logs or boulders to roll down and block the road.

Drop gates will be found along the borders between countries where there is a threat of military invasion. They will be placed at points where vehicles cannot move off of the road to bypass the obstacles. Any massive structures similar to those described above, and with no other obvious function, located in such areas, are probably drop gates.

Figure 13: An overhead dropgate

Terminal Facilities

Because of the extensive network of roads in most areas, terminal facilities are more dispersed than for other transportation systems. Some can be quite large, but many are small and may be difficult to identify. Terminal facilities can be divided into four categories: freight, passenger, maintenance and vehicle storage.

Freight Terminals

Freight terminals deal with the shipping, transshipment or receiving of materials. For packaged materials, a single-story warehouse is used. Loading platforms are present along one or two sides of the building. If material is to be stored at the location, the building can be quite large. A small building indicates that it is mainly concerned with transshipment. There must be enough room around the loading platforms for the trucks to maneuver, as well as an adjacent, normally paved, parking area for waiting trucks. Trucks and trailers will almost always be present.

Bulk materials require special handling and storage. Solids are stored in silos or elevators or are piled in open storage areas. Specialized loading equipment, including conveyors and tipples will be present. Liquids and gases are stored in tanks, and special loading points, sometimes covered, are connected to the tanks

Figure 14: Overview and close ups of a POL transshipment area. Note the covered and open loading bays, and the barrels stored in the open at the bottom of the picture.

by above or below ground pipelines. The presence of a parking area and trucks, which may be specialized vehicles such as tank trucks, indicates that the facility is a road terminal.

Passenger Terminals

Passenger transportation is almost always via bus. Bus terminals are not very distinctive, especially in smaller towns, where a small, nondescript building, or a few rooms in a larger building may serve the purposes of ticketing, baggage handling and waiting area. In larger cities with more bus traffic, the terminal building will be a one or two story structure, with parking areas for the buses. The boarding area may have a roof to protect passengers from the rain, or in large terminals, the buses may drive into the building. Wide roads with rounded corners are present to allow the buses to maneuver. In some cases, the corners of the building may be rounded to provide maneuvering room for the buses. Of course, the presence of buses is helpful in identifying the terminal building.

Vehicle Storage

Most vehicle storage (parking) is in open, prepared areas. Most permanent parking areas are paved, and often are marked to designate parking spaces. Parking areas are easy to recognize. The even tone of the parking lot and regular rows of vehicles are distinctive. There will be easy access to adjacent roads, and the lot will be near a commercial, industrial, military or institutional facility. Military parking areas can be distinguished by the precise arrangement of vehicles and adjacent buildings and the uniform appearance and tone of the vehicles.

Within urban areas, vehicle parking is available in specially designed parking garages. These concrete structures provide several levels of parking spaces connected by ramps. These buildings are often open on the sides, so the different levels are visible from an oblique view. There will be a substantial parapet around the top of the building. Other characteristics are the presence of parking spaces and vehicles on the top of the structure, access roads into the building at ground level and the ramps connecting the different levels. Newer structures use spiral ramps, usually near the corners of the building.

Service and Maintenance Facilities

Servicing of bus or truck fleets is usually accomplished at a central location. The maintenance shop will be a large, single-story building with many large doors. An open parking area is normally adjacent to the maintenance facility. Military motor pool areas provide maintenance services for a unit's vehicles, and are directly adjacent to the vehicle parking area. Open-sided maintenance sheds, butterfly-roofed shelters and grease racks are spaced around an open central area.

Service stations provide fuel and maintenance services for other vehicles. These are normally small and widely distributed along the road network. They may vary

Figure 15: Vehicle maintenance area

widely in appearance, and shelters may or may not be present over the fuel pumps. There are several clues that can aid in the identification of service stations. They are frequently found at road intersections, on street corners, or at highway interchanges. Easy access to adjacent roads is provided. There is usually a paved area for maneuvering, parking and light service. Immediately adjacent to the paved area, and set back from the road is a small, usually one story building with large doors.

Railroads

Introduction

This section discusses all forms of transportation where the vehicles move along a track that both supports and guides the vehicle. In addition to the familiar railroads, this includes tramways, funiculars, cog railways and monorails. Although there are several variations on this form of transportation, the vast majority of rail lines are traditional railroads. The major part of this section discusses railroads, and the more specialized forms are included at the end of the section.

Railroads are an important part of the transportation network in any country. Even in the USA where truck and air transportation are highly developed, trains still carry a majority of the freight.

Railroad Construction

Railroad trains travel on tracks consisting of parallel steel rails which both support and guide the train. A flange on the inside of each wheel keeps the wheels on the track. In order for the train to travel safely, precise alignment and spacing

Product	Percent Carried by Rail
Coal	70 %
Canned and Frozen Food	74 %
Meat and Dairy Products	46 %
Household Appliances	71 %
Automobiles and Parts	76 %
Pulp and Paper	86 %
Timber	78 %
Chemicals	63 %
Primary Metal Products	68 %

Table 1: Percent of US freight carried by railroad (1988)

of the rails is essential. This is accomplished by fastening the rails to cross-members called ties (or sleepers). The ties lay on, and are partially embedded in a layer of coarse gravel, rock or cinders called ballast. The ballast firmly anchors the ties and rails in place, and maintains the vertical and horizontal alignment of the track. The ballast also allows water to drain away, further protecting the track.

The Permanent Way

The term "permanent way," referring to the combination of the track and the ballast, originated in the early days of railway construction. It was used to distinguish between the temporary lines used by the contractors and the finished, or permanent track. The ballast and track are placed on a carefully prepared and graded subgrade (or roadbed). This is composed of rock, gravel and/or earth, and is always built up above the ground level to allow water to drain away from the track. To either side of the subgrade, lateral drainage ditches carry water to the local drainage network.

Originally, ties were made from wooden timbers, but wood can deteriorate quickly, requiring regular replacement. However, wood treated with creosote preservative is still commonly used. Rails were first fastened to the ties by spikes with hooked heads, and spikes are still in common use. Since its invention in 1957, the spring steel "Pandrol" clip has been used on much of the newer tracks. A pair of joint bars (or fishplates) is used to keep the ends of the rails in alignment. Modern, heavy, welded rails eliminate the problems associated with joining rails together. A check rail is sometimes installed just inside the regular rail to guide the flange of the wheel. They are used on curves of short radius and on viaducts and bridges to guard against derailment.

Concrete ties are now often cheaper than wood, and are used wherever possible in Britain and are found in other industrialized countries. Steel ties, which can last for 40 to 80 years, are extensively used in continental Europe. In Switzerland,

70% of the Federal system and all of the narrow gauge systems use steel. Greece, the Congo Republics, and systems in west, east and South Africa use steel ties in 90 - 100% of their track. India has 15,000 km of broad and narrow gauge track with steel ties. Steel ties will enhance the radar signature of the railroad track. It is difficult to determine the composition of the ties, even on the largest scale of panchromatic imagery.

Paved concrete track (PACT) consists of a continuous concrete slab on which the rails are fixed. This eliminates the need for ties and ballast and gives a smoother, more stable base for modern high-speed trains. It is especially well suited for use in tunnels and rapid transit lines. PACT has been used on lines in England, Scotland, France, Japan and New Zealand, especially around tunnels. PACT can be recognized by its very light tone, smooth texture, and the absence of the cross-hatched pattern of the ties.

Figure 1: Railroad roadbed and components

Alignment

Trains are not able to negotiate sharp curves or steep grades. Therefore, railroad tracks will always exhibit gentle curves, and rarely will gradients exceed three per cent. The capacity required of a railroad line dictates the number of tracks or passing sidings, as well as the maximum speeds. The maximum speed, in turn, dictates the alignment, the minimum radius of curves and maximum grades. These, in combination with the terrain, control the number and size of cuts, fills, bridges and tunnels, all of which help minimize curves and grades.

Railway curves are measured in various ways. In continental Europe, they measure the radius of the curve in meters. In Great Britain, the radius is measured in

Locally, particularly around older cities, cut stone (sett) or brick pavements may be used. These areas are rapidly being replaced or paved over with asphalt.

Figure 7: A multiple-lane road (four lanes). Such roads are almost without exception hard-surfaced.

Photo Interpretation Training Course

Transportation

Cultural Features 45

Figure 2: Methods of curve measurement

"chains" (1 chain = 66 ft = 20.12 m). Not to be outdone, U.S. railways measure curves in degrees of arc, where the arc is defined by a chord 100 meters long. The broader the curve, the smaller the angle. For example, a 10° curve has a radius of 175 meters, while a 1° curve has a radius of 1,750 meters. Figure 2 illustrates these three methods of measurement.

Curves may be super elevated (canted), where the outside rail is higher than the inside. This moves the center of gravity of the train toward the inside of the curve and allows the train to take the curve at a higher speed. In addition, transition curves, with gently increasing cant and decreasing radius, are needed to ease a train into and out of curves.

Track Gauges

The gauge of a railroad is the distance between the inside edges of the two rails. Many gauges have been used around the world, but modernization of railroads has led to increased standardization. The most commonly used gauges are listed in Table 2. The "standard gauge" of 4 ft 8 1/2 in (1.435 m) has been adopted throughout North America, most of Europe, North Africa, China, and other countries scattered around the world.

Running Direction

In order to allow trains to run in both directions on a single-track line, passing sidings (or passing tracks) are provided at intervals along the line. These are parallel lengths of track, connected at both ends to the main line. They can be recognized as passing sidings as they will be located away from other rail facilities, there will be no loading facilities, adjacent structures or connection to other transportation networks. They will be long enough to accommodate the longest train normally traveling that line.

Figure 3: Measurements of standard (USA) and narrow gauge railroad beds

other roads or railroads.

Figure 8: A four lane divided highway, without a median

Photo Interpretation Training Course

Chapter 3

46 Cultural Features

On double-track lines, the trains will run on either the left or right track, depending on the convention adopted by the country (or sometimes by individual rail lines). Right-hand running railways are found in Canada and the USA (except the Chicago & Northwestern Railroad), Russia and the former Soviet Republics, some sections of China and Austria, Bulgaria, the Czech and Slovak Republics, Denmark, Finland, Germany, Hungary, the Netherlands, Norway, Poland, Turkey and "Yugoslavia." Parts of France (Alsace and Lorraine) were under German administration when the lines were built, and are still right-running. Other countries use left-running, or have no double-line railways. Modern signaling methods have allowed several railways in Europe and the USA to run trains in either direction on both tracks.

Electrification

Using electricity to power locomotives is more efficient, and less costly than using diesel engines. However, the high cost of installing the wiring along the rail line makes electrification economical only where there are high volumes of traffic over relatively short distances. Electrified railroads are more common in Europe and Japan, where high volumes of traffic run between closely spaced cities. In other parts of the world, electrification is limited to a few high-traffic lines, and to urban rapid-transit/commuter lines.

Figure 4: Overhead electrified railroad, shadows and components

Most electrification is via cables suspended over the track. On single-track lines, the cable is suspended from an arm mounted on simple poles or towers evenly spaced along one side of the track. On multiple-track lines, or where the track passes through a yard, pairs of poles or towers support either a gantry or a trans-

Figure 5: Overhead view of an electrified commuter train. Note the pantographs present on each car, indicating that both cars are powered

Photo Interpretation Training Course

Figure 6: Catenary system

Figure 7: Railbed for a third-rail electrified line

verse cable (catenary system) from which the power cables are suspended. Since the poles are small and set close to the tracks, they may be difficult to see on imagery, especially on single-track lines. Sometimes a regularly spaced line of light-toned scars marks the base of the poles. On multiple-line tracks, the gantries are usually visible, though catenary systems may only have gantries at intervals. If poles or gantries are not visible along the track, examine the rail yards, where the gantries would be larger and more readily visible. If there is a train on the track, look for the pantograph on top of the locomotive. This is a structure of articulated rods that remains in contact with the power cable. Small electrical substations are located at intervals along the track.

Some rail lines, particularly commuter lines in urban areas, are electrified through a third rail which carries the current. The electrified rail is usually set outside the primary rails, but may occasionally be placed between them. These third-rail systems are difficult to discern on imagery, unless the resolution allows you to see the actual number of tracks.

Figure 8: Aerial view of a third-rail electrified track

Signals

Railroad signals are small and difficult to locate on imagery. For cartographic purposes, they have little significance. However, on multi-track lines and in rail yards, the signals may be mounted on gantries built across the tracks. The analyst

Figure 9: Aerial view of a dual track railroad with signals and other trackside features

should be careful to avoid confusing these occasional signal gantries with the regularly spaced electrification gantries.

Operational Status

There are three categories of operational status for a railway line, operational (in regular use), abandoned (intact but not in use) and dismantled (track and bridges removed). Even casual examination of a dismantled line will reveal that the tracks and bridges have been removed. Yet the graded right-of-way is still present and offers an alternative route for military vehicles.

The distinction between operational and abandoned lines is not as simple. The presence of rolling stock, of course, verifies operational status. Abandoned tracks will develop a layer of rust on the rails, eliminating the reflections seen on operational lines. In addition, vegetation will grow through the ballast, giving the rail bed a mottled texture. Where trees grow near the tracks, limbs growing across the right-of-way may be visible.

Terminals and Facilities

Railroad terminals can be divided into three main categories: loading and unloading of passengers and freight, storage or sorting of trains, and repair/maintenance facilities. Two or more of these functions may occur within the bounds of a large railroad facility, but the differing requirements, and thus the appearance, of each allows them to be identified and separated.

Terminals

Terminal facilities can be divided into four categories, passenger terminals, freight terminals, freight transfer stations, and freight storage areas. At larger facilities, these functions each have their own area, and can be easily delimited. In small stations, however, two or more functions may be combined in one area.

Terminals come in two basic configurations, through terminals and dead end terminals. In a through terminal, the tracks diverge entering the loading/unloading

area, and converge again on the other side to rejoin the main track. Through terminals can be used by trains passing in either direction. A dead end terminal is connected to the main line at one end only, and the tracks fan out into the loading/unloading area. In either case, loading platforms and connections to other transportation networks will be present.

Passenger and freight terminals are usually located close together, particularly in urban areas. They are characterized by tracks which are separated by platforms, sheds, stacks of goods, etc. Outlying areas are served by small stations and depots, or by isolated freight yards.

Figure 10: Through and dead end terminals. Note the freight depot adjacent to the passenger terminal on the through configuration.

Passenger Terminals

Stations and depots are smaller facilities along a railroad line where passengers can board or leave the train. These facilities normally consist of a small building adjacent to the tracks, with a small vehicle parking area. There will be at least one siding on which the trains stop for loading, with adjacent loading platforms that may or may not be covered. If there is more than one platform, access to other platforms is via pedestrian tunnels. Stations and depots are almost always of the through type, allowing trains to pull in and out and continue in the same direction.

Passenger terminals are large facilities, characterized by a large terminal building with a covered concourse immediately adjacent to the loading platforms. Abundant vehicle parking is available, as well as easy access to other transportation. The loading platform area consists of several closely spaced tracks with covered platforms between them. These distinctive covered platforms are easily visible between the tracks. Terminals may have either a through or dead end configuration. At through terminals, access to the platforms is through pedestrian overpasses. Most large passenger terminals have a large plaza across from the terminal entrance.

Freight Terminals

The presence of a siding or spur leading to a facility indicates that at least some materials enter or leave the facility by rail. These industries, warehouses, transshipment areas, etc., will have loading docks with specialized equipment to handle the freight, and either open or enclosed storage areas.

Freight terminals can also be of the through type, but most have a dead-end configuration. Freight handling requires larger spacing between the tracks, giving these areas more of a fan shape. Long, narrow freight sheds with adjacent tracks are present for storage of materials. These may have a distinctive sawtooth shape where individual cars are backed in for loading. Some areas are set aside for transshipment of freight to trucks. These "team tracks" are widely spaced, have open areas between them with easy access to roads. A set of closely spaced holding tracks is often present, where waiting cars are stored.

Transfer of freight to ships or barges occurs at ports and harbors, where the tracks will extend out onto the piers and wharves where the ships are berthed. Extensive warehouses or other storage facilities will also be present. (See also the section on Ports and Harbors.)

Figure 11: Diagram of a terminal area. Note the through type passenger terminal and dead end freight terminal.

Facilities for storage of freight will occupy a considerable portion of the freight terminal. Bulk materials may be stored in open areas. Warehouses and freight sheds are large, single-story frame structures of light construction. Metal and wood structures, as well as masonry buildings, are common. Depending on the materials being shipped, specialized structures, such as POL tanks and grain elevators, may be present. These and other storage facilities are discussed in detail in Chapter 4.

Railroad Yards

As railroad cars proceed from their origin to their destination, they must be assembled into trains for shipment, and disassembled upon arrival. They may be detached from one train and reattached to another enroute. This assembly, disassembly and reassembly of trains requires an extensive area of tracks and occurs in various through and dead-end type railroad yards. Car handling yards are characterized by their through type configuration, closely spaced tracks and absence of buildings, platforms, etc.

Arriving trains are kept in a receiving yard until they can be disassembled. These yards are always of the through type, and are smaller than the classification yard.

Cultural Features **51**

Figure 12: Oblique view of a freight terminal where POL products are loaded to railroad tank cars (right side of photo) and to tank trucks (left side of photo). The rail terminal has a dead end configuration, and a holding yard for cars waiting to be filled can be seen above and to the right of the loading platforms. Note the darker tone of the ballast around the rail lines, as opposed to the surrounding concrete pavement.

Figure 13: A ground view of the terminal shown in figure 12. Note the covered loading equipment between each pair of tracks, and the darker tone and coarser texture of the gravel ballast of the rail bed.

Photo Interpretation Training Course

Figure 14: Simple and complex railroad yards. In the top and center examples, the traffic flow would proceed from left to right. The complex yard on the bottom could handle traffic in two directions. This yard is located on a dual-track, right running line, where traffic entering the complex always enters on the right side.

Cars are uncoupled from the inbound trains and moved into the classification yard (sometimes called a marshalling yard) by a small switch engine. Classification yards are also of the through type. Upon assembly, the trains may be moved into a small, through type forwarding yard, until the train is scheduled to depart. A small set of tracks may be provided for storage of empty or damaged cars. This holding yard will be a small area of through or dead end tracks.

The cars are sorted and regrouped by switching them onto the appropriate track in the classification yard. The switches are operated from a control tower overlooking the yard. At small or out-of-date yards, the movement of cars is done solely with a switch engine. The switches may also be operated manually at these facilities. At others, the yard may be constructed on an incline, so that as cars are uncoupled they would roll out of the receiving yard and be switched onto the proper track. A switch engine would perform only minimal work in this type of operation.

Most classification yards now use a variation of the gravity method. A hump is constructed

Figure 15: Railroad control tower

Figure 16: Flat (upper) and gravity (lower) classification yards. The gravity yard can be recognized by the presence of retarders on the tracks, by the slope of the ground (on stereo imagery) and sometimes by the absence of a switch engine. A receiving yard may be present at both types of facilities.

between the receiving and classification yards. A switch engine pushes the cars up the ramp, where they are decoupled and allowed to roll down the opposite side, where they are routed to the proper track. The speed of cars rolling into the yard is controlled by retarders, long bars which squeeze against the flanges of the wheels. The retarders may be operated through the switch control tower, or there may be a separate retarder control tower. The retarders are readily visible even at medium scales as dark rectangular areas where the tracks diverge into the classification yard.

The receiving, classification and forwarding yards are arranged end to end. In smaller yards, the forwarding yard, and even the receiving yard may be absent.

Figure 17: Side view and aerial view of a hump classification yard

Chapter 3

54 Cultural Features

Figure 18: Diagram of a railroad yard and terminal complex. The classification yards are on the left, the terminals are on the right, and repair and maintenance facilities are centrally located.

In large facilities on double line tracks, two sets of yards may be present for traffic moving in both directions. The holding yard, if present, may have any configuration, and would be located wherever sufficient space is available (see figures 14 and 18).

Photo Interpretation Training Course

Repair and Maintenance Facilities

For reasons of convenience and centralization, facilities for maintenance and repair of rolling stock will be present adjacent to rail yards and terminals. Tracks for the storage of cars awaiting repairs or being repaired form yards mostly of the dead-end type. Individual configurations depend on the space available at the facility. Repair and maintenance facilities contain a number of large buildings with tracks adjacent to or entering the buildings. The buildings are of substantial construction and have the sawtooth or monitored roofs typical of industrial facilities.

The presence of tracks leading into large, single-story buildings and rolling stock on the tracks, and the absence of platforms, loading facilities or good road access are the keys to identification of car repair facilities.

Fueling facilities are also present in this area. In smaller facilities, both cars and locomotives may be serviced in the same building. Most facilities have separate locomotive repair areas. Locomotive repair areas are identified by the presence of a turntable and roundhouse.

Figure 19: Typical arrangement of facilities at a railroad repair and servicing terminal

Figure 20: Roundhouse and semi-roundhouse. A semi-roundhouse can occupy any fraction of the perimeter of the turntable, and all or part of the remainder may contain open tracks for storage of locomotives.

A turntable is a section of track set on a rotating platform in a circular hole. In its simplest configuration, it is used to turn a locomotive around on the track. In repair facilities, there are several tracks radiating from the turntable, leading to a circular or semi-circular building that entirely or partially surrounds the turntable. This building is called the roundhouse, and contains equipment for

Figure 21: A turntable and associated service facilities

repair of locomotives. The circular shape of the facilities make the roundhouse and turntable easy to locate and identify.

Some repair facilities make use of a transfer table. This is located between two buildings, and consists of a section of track that can be moved laterally, to move a locomotive from one building to a particular stall in the other building.

Commuter Lines/Trolleys

Within major urban areas, commuter traffic is often carried by specialized rail lines. Although some are of standard gauge, most are of narrow gauge. Electrification of commuter lines is almost universal. Third rail electrification is used where the right of way can be isolated. In addition, the cars may be smaller in size than standard rail cars.

The tracks may be placed on their own right of way, and can be underground, on the surface, or elevated, for all or parts of the route. In some cities, the rail lines are set in the middle of existing roads (trolleys). These can be difficult to

Figure 22: Overhead electrified commuter lines

detect; look for the overhead electric lines, and wider than normal streets. At the end of the commuter lines, a turning loop may be visible.

Stations for commuter lines are usually small, and may be only a shelter. Larger stations will be located at intersections with other transportation facilities, such as airports, bus depots and railroad terminals. Stations in the suburbs may have larger commuter parking lots.

Logging Railroads

Logging railroads are temporary tracks of light construction built to carry logs to the sawmill. They are normally of narrow gauge, and will have sharper curves and steeper grades than regular rail lines. They are found in forested areas where logging operations are active. The lines often branch several times as they enter the logging area. Cleared ways without tracks mark where the tracks were previously located and then abandoned as logging operations moved into a new area. Their location in a forested area, sharp curves, and branching into an area with no obvious destination are keys to the identification of logging railroads.

Cog Railways

Cog railways are used where a rail line must be built along a steep grade. Locomotives have geared wheels which engage a toothed center rail. These railways are almost always of narrow gauge with correspondingly smaller cars. The presence of the center rail and the steep grade of the track are indicative of cog railways.

Figure 22: Diagram of a cog railway track. Note the distinctive toothed center rail.

Monorails

The term monorail refers to a class of vehicles that travel on a single large rail. The cars may either ride on, or be suspended from the rail. Most monorails are commuter lines, or are used for moving people around large facilities such as airports or amusement parks. A few high-speed, inter-city lines have been constructed using a monorail.

When the cars ride on the monorail, the line will appear similar to a normal commuter rail line, except that close examination reveals the presence of only a single, large rail. Suspended car monorails are more distinctive, as the imagery will show the rail and the structures supporting the rail. The track can vary from

Bridges

Introduction

Bridges are the most vulnerable part of any transportation system. The loss of a key bridge (or bridges) can significantly reduce or paralyze the movement of troops, armaments or supplies. Therefore, knowledge about an area's bridges is vital to military planners. The location, construction and capacity of all bridges, as well as the identification of alternate routes and bypasses are key factors in the planning and conduct of military operations.

A bridge is any structure (other than an earthen fill) providing passage for a transportation route over an obstacle. The type of bridge built at a particular location depends on several factors. Most important are the purpose of the bridge, the topography of the site, and the labor, materials and technology available. However, aesthetic considerations, and the previous experience of the designer also effect the design of the bridge. There is often no single best bridge design for a particular situation.

Changes in technology have resulted in an evolution of bridge construction methods. New materials and designs, especially within the last 200 years, have dramatically changed the appearance of bridges. Because the bridges found in a geographic area are usually of different ages, a variety of bridge types and materials can be expected.

Figure 1: Basic timber beam bridge

The earliest type of bridge consisted of a log dropped across a gap. This simple beam bridge was improved by cutting and shaping the wood into timbers, and assembling them into a continuous deck. These bridges were limited in size by the relatively low strength of wood, which required massive timbers to bridge even short gaps. Wider gaps required numerous intermediate supports. These early wooden structures were limited to light loads and short spans, until the invention of the truss. The construction of timber truss bridges reached its peak in the 18th and early 19th centuries. But wood deteriorates quickly, and is susceptible to damage by fire. Timber bridges require constant repair, and few are left today.

Figure 2: Basic masonry arch bridge

The invention of the masonry arch bridge, more than 3,000 years ago, allowed the construction of longer spans able to carry heavy loads. The Romans made extensive use of this design to carry aqueducts as well as roads. The construction of extensive canals during the Industrial Revolution utilized masonry arch structures to carry the canals over obstacles. These massive masonry bridges proved stronger and more durable than wooden bridges, and many are still in use today. But the construction of large masonry arches was a

Figure 3: A steel truss bridge with several through-type, polygonal chord spans on solid concrete piers (background) and several deck-type, double-Warren spans on steel trestle piers (foreground). The through spans maximize the under-bridge clearance for ships travelling up the main channel.

Figure 4: Primitive timber and rope suspension bridges. Mainly for pedestrian use, bridges like these are still in use in undeveloped areas.

major engineering task, and required a lot of labor. This made them expensive and limited their use.

The development of iron and steel structural members gave rise to a new generation of truss bridges in the late 19th century. The parts for metal truss bridges were easily transported and assembled, reducing construction time and thus cost. The durability and greater strength of metal made truss and girder bridges popular on the expanding road and railroad networks.

A primitive form of suspension bridge, still in use in some areas, consists of three ropes suspended across a gap. The lower rope serves as the floor while the other ropes are used for balancing as one walks across, or two lower ropes may support a flimsy wood deck. Further development of suspension bridges had to wait for the development of a material with high tensile strength. With the introduction of iron chains in the early 19th century, and later, steel cables,

Figure 5: Modern cable-stayed suspension bridge (under construction). Note the massive towers and the concrete bents supporting the approach spans.

the construction of large suspension bridges became possible. They are still the most economical type of bridge for crossings requiring wide clearances.

Concrete was not widely used for bridges prior to the 19th century, because of its poor tensile strength. The introduction of reinforced concrete, and more recently, pre-stressed concrete, made the design of concrete bridges possible. The steel reinforcing bars add tensile strength and allow concrete to be used for structural members in tension. Pre-stressing the reinforcing bars increases the strength and stability of the structure. The use of concrete in bridge construction has been increasing steadily since the end of the 19th century.

Figure 6: A concrete arch suspension bridge. This design is also referred to as a bowstring arch.

Bridge Structural Elements

All bridges are composed of the same basic structural elements. The part of the bridge that spans the gap is called the **superstructure**. This includes the floor of the bridge and the structural elements that provide strength and rigidity. The **substructure** includes all of the elements upon which the superstructure rests. **Abutments** are the foundation-like structures that support the ends of the bridge. Intermediate supports on longer bridges are provided by **piers**, **piles**, **bents** or **trestles**. The section of a bridge's superstructure between abutments, between intermediate supports, or between an abutment and an intermediate support is called a **span**.

Some DMA product specifications use the terms superstructure and substructure differently. For example: In DFAD, "superstructure" refers only to structural elements that extend above the road or railway crossing the bridge. When describing a bridge for a particular product, be sure to verify the usage of terms with the product specifications.

Figure 7: Diagram showing the basic components of a bridge

Bridge Substructure

Just as the foundation serves as a stable base for a house, the abutments form the stable base upon which the ends of the bridge rest. These concrete or masonry (occasionally wooden) structures protect against undermining of the bridge by erosion of the banks and approaches. The abutments also provide support to the earthen fills of the approaches, where the route is graded to the level of the bridge. The abutments are not normally visible on vertical imagery.

The distance that can be spanned without intermediate supports depends on the bridge structure type and materials. Bridging across wider gaps requires the use of intermediate supports. A pier is a solid (masonry or concrete) structure that provides a continuous support across the width of the bridge. A bent is a simple structure consisting of a single row of piles (pile bent) or posts (trestle bent), cross-braced and surmounted by a cap. A structure consisting of two or more adjacent bents braced together is also called a pier (pile pier or trestle pier). These supports may be composed of wood, steel or concrete members.

Occasionally, a continuous framework is used to support the length of a bridge between the abutments. This kind of structure (wood or steel) is called a trestle.

Figure 8: Bridge abutments

Figure 9: Several common varieties of bridge piers. Piers will only be visible on imagery taken at an angle to the vertical. Shadows of piers may also be visible.

Figure 10: Piles

Figure 11: Bridge bents

Figure 13: A bridge supported by a wood trestle

A bridge supported by a trestle does not have individual spans, as the trestle provides continuous support along the length of the bridge.

Figure 12: Trestle piers

Although piers, bents and trestles are hidden by the bridge on vertical imagery, when the sun angle is right, the shadows can reveal the types of supports present.

Bridge Superstructure

The bridge superstructure is composed of a **floor system**, which carries the transportation route, and the **supporting structure**, which supports the floor system and gives the bridge its strength. The surface of the floor system, where the traffic is carried, is called the **deck**.

The superstructure is composed of **simple** spans if each span is a distinct structural element. When the structural element runs uninterrupted across more than two supports, it is called a **continuous** span structure. A **cantilevered** span is one where the structural element is balanced on one of the supports.

The relationship between the floor system and the supporting structure is an important factor in describing bridges. When the supporting structure is entirely underneath the floor system, it is called a **deck bridge**. When the supporting

structure is entirely above the floor system, it is a **through bridge**. When the floor system is located at an intermediate position, it is called a **semi-through** or **half-through bridge**.

Various design principles are used to impart strength to the supporting structure. These design types are described under **Bridge Classification**. The materials used in the construction of the bridge may change its appearance, but the bridge type will still be recognizable.

Skew Bridges

Bridges are normally built perpendicular to the obstacle they cross, and the route is then adjusted to the position of the bridge. This minimizes the length of the bridge, and thus minimizes construction costs. In some cases, especially on major highways and railroads, changing their alignment for small bridges is more expensive than the cost of bridging the gap at an angle. In these cases a **skew bridge** is constructed. The superstructure is built parallel to the route's centerline, while the substructure is aligned with the obstacle being crossed.

Bridge Classification

There are several factors that can be used to classify bridges. Characteristics such as function, composition, design criteria, etc., can be used to divide bridges into categories. These factors are summarized in **Table 1**. The most visible distinctions are those related to bridge design. Therefore, bridge design types will be addressed individually, and the other factors will be discussed within these sections.

DMA specifications differ widely in the way they classify and describe bridges. These product and construction specs are often internally inconsistent as well. For example, the terms cantilever and deck are often used to describe bridge design types. For some types of bridges (eg. the truss arch suspension bridge in figure 35), placement into a specific category is difficult under any specification. When classifying bridges, the analyst should study the specifications and assign the bridge to the most appropriate category.

FUNCTION	MATERIAL	TYPE	INTERSPAN RELATION- SHIPS	BRIDGE FLOOR POSITION	NAVIGATION CLEARANCE
Railway	Timber	Beam (Stringer)	Simple	Deck	Fixed
Highway	Masonry	Girder	Continuous	Through	Swing
Viaduct	Iron	Truss	Cantilever	Semi-through	Lift
Footbridge	Steel	Arch			Tilt (Bascule)
Aqueduct/ Canal	Concrete: reinforced or prestressed	Suspension			Other
Combination					

Table 1: Bridge Classification Criteria

Figure 15: Diagrams of through type, simple truss bridge showing critical dimensions

Figure 16: Diagrams of several bridge types, showing critical dimensions

Figure 17: Diagram of bridge span relationships

Beam (Stringer) Bridges

A **beam bridge** is a simple structure, consisting of two or more parallel beams (sometimes called stringers) laid across the gap. The bridge flooring is supported directly by the beams. This type of structure is suitable only for short spans. Wooden bridges will have spans of less than 20 feet (6 meters), steel and concrete structures will have spans of less than 40 feet (12 meters). This type of bridge is commonly used for highway overpasses. Since the supporting structure is below the floor of the bridge, these are always deck bridges.

Beam bridges cannot be conclusively identified on vertical imagery. Deck-type highway bridges with short spans are usually beam bridges. The shadow will show the underside of the bridge to be parallel to the deck.

A **slab bridge** is a variation where the floor system and supporting structure are combined into one piece, a rectangular slab of reinforced or prestressed concrete. This slab sits directly on the abutments. Slab bridges are used to bridge short gaps (< 20 feet or 6 meters) on minor roads.

Figure 18: Basic beam bridges. Many highway bridges are merely larger versions of this simple design.

Figure 19: Slab bridge

Girder Bridges

A **plate girder** is a large beam fabricated from steel plates. Because of its large size and deep cross-section, it provides more support than smaller beams. Thus, girder bridges can carry heavier loads and span longer gaps than beam bridges. Their greater strength makes them particularly useful for railroad bridges.

The most common form of girder has an I-shaped cross section. Two parallel girders form the supporting structure, and the floor system is set between the girders. The girders can be placed below the floor system (deck bridge), but the large size of the girders then restricts the clearance under the bridge. For this reason, it is more common for the floor system to be placed at the base of, or at the midpoint of the girders (through or semi-through bridges).

When the bridge is of the through or semi-through type, the plate girders are easily visible. For deck type bridges, the only clues to identification are the greater thickness of the supporting structure, and the relatively short span length (<100 feet, 30.5 meters). Continuous span girders, extending across the intermediate supports, can bridge longer gaps. As noted above, they are more common on railroad bridges than on highway bridges.

The **box girder** is another form which has increased in popularity because of its strength, versatility and economy of materials. A box girder has a square or rectangular cross section and is hollow. They are almost always placed as supports under the floor system on deck bridges. They can be simple spans, but continuous spans are also used. Their superior strength allows for spans of great length.

Note: For some DMA specifications, box girder construction is classified as a Beam/Stringer bridge. The term "Girder" usually implies a large plate girder with an I-shaped cross section.

Box girder bridges are difficult to identify on vertical imagery. They are characterized by their simplicity of design, greater span length and the lack of other supporting structures, such as trusses, arches, etc.

Figure 20: Various configurations of plate girder bridges. Because of their great strength, plate girders are most commonly used on railroad bridges. Note the cantilever design of the last example. When identified by its shadow on vertical imagery, this may be mistaken for an arch bridge.

Plate girder bridges are almost always made of steel. Some newer construction utilizes girders made of prestressed concrete, which can be identified by their very light tone. Box girders are normally concrete.

Truss Bridges

A truss is composed of a series of relatively small girders (members) joined together in a triangular pattern. This triangular bracing gives it the strength and rigidity of a solid beam, yet the structure is much less massive than a plate girder of equivalent strength. Truss members are subject to either compression or tension. Compression members are often thicker than the tensile members, but can also withstand a tension load. The small size of the individual members makes them easy to transport and assemble. Because of their strength, versatility and ease of construction, truss bridges are widely used around the world.

Each truss has a top and bottom girder (the **upper** and **lower chords**). The upper chord carries the main compression load, and may be parallel to the lower chord, or it may be composed of sloped or curved sections. At each end, a vertical or inclined post forms the end member of the truss. Two parallel trusses form the supporting structure of a bridge. The trusses are normally, but not always, cross-braced with each other. If the trusses are not cross-braced, it is known as a **Pony Truss**.

Figure 21: Elements of a truss. The combination of these cross-braced elements results in the structural equivalent of a beam or girder.

Figure 22: Basic truss shapes. The arrangement of tension and compression members within the truss determines the actual truss type.

Figure 23: Basic truss types. Although these examples have parallel top chords, for most truss types they could be curved or slanted.

Truss bridges may be through, semi-through or deck type. They may have simple spans, with a separate truss on each, or the truss may be continuous over several spans. The cantilevered span achieved its greatest expression through the steel truss.

Early truss bridges were constructed entirely of wood. Later structures used iron for the tensile members and wood for compression members. Iron eventually replaced all of the wood, and by the year 1900, trusses were made entirely of steel. Recently, pre-stressed concrete trusses have been used to replace the steel. There are few surviving wooden truss bridges.

There are many forms of trusses, as illustrated in this section. The earliest form used on wooden bridges is the triangular **King-post truss**, with one vertical tension member. A series of king-posts were sometimes strung together on longer bridges. The **Queen-post truss** is similar, but has a second tension member. The problem with wooden bridges was that they tended to sag in the middle. To counter this, Theodore Burr added an arch to a multiple King-post truss. The **Burr arch truss** was patented in 1817 and remained the most popular of the arch reinforced truss bridges. Another popular truss type was patented by Ithiel Town in 1820. The **Town lattice truss**, as the name implies, was composed of a lattice of relatively small members, which form a long, stiff structure. Since this lattice truss was not susceptible to sagging, it was also widely used. Many other truss designs were developed in the early 19th century, but most found only limited acceptance.

By the mid-19th century, iron bridges were rapidly replacing wooden structures. The **Howe truss** utilized vertical iron tension members and diagonal wooden compression members. A few were built later entirely of metal. The latter part of the 19th century saw the development of several truss types composed completely of iron or steel. Some of the more popular were the **Bollman truss**, the

Figure 24: Basic truss bridge types. 1) A through bowstring truss, where all posts and diagonals are tension members; 2) A deck bowstring truss, this is not a true bowstring, but a variation on a Pratt truss; 3) A through Warren truss, recognizable as being made of concrete by the thickness of the members and the lighter tone; 4) A continuous span, deck-type Howe truss; 5) A continuous span through truss, centered on a Baltimore truss, which gives the longer central span added strength; 6) The Wichert truss is actually a hybrid structure. The central span is suspended beneath a cantilevered truss arch.

Fink truss, the **Post truss** and the **Thacher truss**. There were, however, three truss types that became very popular, and were adapted to many situations.

The **Pratt truss**, patented in 1844, used vertical compression members and diagonal tension members, just the opposite of the Howe truss. Its great strength, simplicity and versatility allowed it to be used in a variety of situations. Several variations were developed from the basic Pratt design. For additional stability, the diagonal tension members were extended across two or three compression members (**double-intersection Pratt** or **Whipple truss** and **triple-intersection Pratt truss**, respectively). Other variations include the **Parker truss**, **camelback truss**, **Baltimore truss**, **Pennsylvania truss** and the **lenticular truss**. The latter is unusual in that both the upper and lower chords are curved, giving the truss a lens-shape.

In 1841, the first **bowstring arch truss** was patented. A bowstring arch truss is a hybrid between a truss and an arch. It consists of a curved upper chord which

Figure 25: Some of the many possible variations for truss bridges

acts as the compression member, and a horizontal lower chord tension member. They are tied together by vertical and/or diagonal tension members. This proved to be a light weight, inexpensive, yet sturdy design, and was widely used in highway bridges, particularly in rural areas.

Patented in 1848, the **Warren truss** was slow to gain popularity, particularly in the U.S., but eventually became the favored design for truss bridges. It is different from previous designs in that the diagonal members are designed to carry both tensile and compressive loads. Thus the Warren truss is characterized by girders of a uniform size. Variations include the addition of vertical members, or extension of the diagonals to form a double-intersection Warren truss. Most

Figure 26: Various truss types and their shadows. Note how the truss under the deck bridge is revealed by its shadow.

modern steel truss bridges, as well as newer prestressed concrete truss bridges, use the Warren truss or a variation.

The lattice framework of the truss is distinctive and easy to recognize on vertical imagery. On through and semi-through bridges, the truss is readily visible. The shadow of the truss is the best recognition factor. It is often clear enough to identify the truss type, even on a deck bridge. Trusses are almost always made of steel (or iron in older bridges). New prestressed concrete trusses can be identified by their light tone and the greater thickness of the structural members.

Arch Bridges

The first major development in bridge construction was the **masonry arch**. An arch is the only structural form in which there is no tension. Therefore, larger bridges can be built without using materials of high tensile strength. Until the development of timber trusses in the early 19th century, and the mass-production

Photo Interpretation Training Course

of iron shortly thereafter, the masonry arch was the only structural form available for construction of larger bridges.

The first reliable report of a masonry arch bridge refers to one built over the Nile River in 2650 BC. The oldest surviving bridge is a masonry arch built about 850 BC over the River Meles at Izmir, Turkey. The Romans refined the arch, and many examples of Roman bridges and aqueducts remain. Masonry arch bridges are found today in many parts of the world.

The basic masonry arch bridge consists of a row of shaped stones that form the arch. This is the structural backbone of the bridge. The spaces between the arch and the deck of the bridge (the **spandrels**) can be filled in with masonry, forming a solid structure. On larger bridges, however, it requires a massive amount of material to fill in the spandrels, so an **open spandrel** structure consisting of a series of smaller arches or piers is used.

Iron and steel proved to be well suited for the construction of arch bridges. In fact, the first iron bridge built was an arch span (Coalbrookdale, England, 1779). For longer spans, the metal structures proved to be more economical than the labor-intensive masonry arches. Span lengths were increased as well. A steel arch can span a gap nearly as wide as a cantilever, though both are surpassed by sus-

Cultural Features 77

Figure 30: Several variations of arch bridges and their distinctive shadows

pension spans. Metal arches can be through or semi-through as well as deck-type structures. Few metal arches consist of a simple curved beam, most are arch-shaped trusses.

Reinforced concrete was used for construction of arch bridges starting in the late 19th century. Concrete bridges rapidly gained in popularity because they used locally available materials and could be built with relatively unskilled labor. Reductions in the amount of concrete required were accomplished by the use of open spandrel designs.

In addition to the traditional deck bridge, a through-type concrete arch structure is also used. The rainbow arch is actually a hybrid between an arch and suspension bridge. Similar to a bowstring truss, the floor system is suspended from the supporting arches.

The surest recognition factor for an arch bridge is the shadow. Some trusses with curved, top chords, such as the bowstring or camelback trusses, may be confused with an arch. Shallow-arched concrete bridges can appear identical to cantilevered spans. The difference between the two is in the way the load is carried. A definitive distinction can only be made if ancillary information is available

Suspension Bridges

Outside of primitive rope bridges, the construction of **suspension bridges** had to wait until a material of substantial tensile strength was developed. The first suspension bridges used iron chains. This method was used in China and Japan several centuries ago, but was first used in the West in Prussia in 1734. Modern suspension bridges utilize the high tensile strength of steel cables to span wider gaps than possible (or economical) with any other structural form.

The traditional suspension bridge consists of two heavy cables, anchored to the abutments and draped over two large rectangular towers. Smaller cables connect the floor system to these **catenary cables**. These are usually all steel structures, though a few bridges have masonry or reinforced concrete towers. In addition, massive abutments are needed to anchor the ends of the cables.

Photo Interpretation Training Course

Figure 31: The structural elements of a suspension bridge

Figure 32: The distinctive shadow of a typical suspension bridge

The tall, massive towers and long spans are distinctive, and are usually easy to see, especially on stereo imagery. A good shadow allows for quick identification, as it reveals the towers, catenary cables and often the suspension cables as well.

A relatively recent improvement upon the suspension bridge design is the **cable-stayed box girder** bridge. As the name implies, it is a box girder bridge which has been augmented by suspension cables to increase the span length. Instead of using a pair of catenary cables, the suspension cables are directly tied to the tower. The tower itself is a slender structure of steel, and the cables for both sides of the structure may run through the center of the tower. Although most bridges have two towers, some short span bridges have only one. The shadow reveals the tall slender tower with the suspension cables radiating from the top.

As noted above, through arch bridges can also be classified as suspension bridges, except that the supporting structure is an arch rather than a catenary cable. The arch extends above the deck of the bridge and cables suspended from the arch support the floor system. These bridges are difficult to distinguish from trusses with curved top chords. If a shadow is visible, the shadows of the vertical suspension cables will be parallel, as opposed to the angular shadows of the truss members.

Figure 33: Four variations on the basic catenary suspension bridge design

Figure 34: Variations of the suspension bridge design

Suspension bridges are almost always steel structures. A few bridges, particularly of the arch type, have used prestressed concrete for the supporting structure and sometimes even the suspension cables are replaced by prestressed concrete members.

Figure 35: An arch suspension bridge

Cantilevered Bridges

Cantilevered bridges are often classified as a bridge design type. However, the term "cantilever" refers to the relationship of the bridge's supporting structure to its piers and abutments. As mentioned previously, a simple span structure is supported at each end by an abutment or pier, while a continuous span structure is supported at each end and by one or more intermediate piers. A cantilevered structure, however, is balanced on its supporting pier. To increase the distance between piers, a **suspended span** may be inserted between two cantilevers (see Figure 36).

Any of the previously mentioned bridge design types can be constructed as cantilevered spans. The easiest to identify is the cantilevered truss, on which the key recognition factors are the most visible. The supporting structure is continuous across the pier, and it is the most massive (tallest) directly over the pier, tapering off to both sides. The suspended span, when present, is a parallel or curved top chord truss, which can be distinguished from the tapered cantilevers. Plate girder and beam bridges also utilize cantilever spans, but in most cases, these are difficult to identify, especially on vertical imagery. Some cantilevered bridges closely resemble arch bridges and may be difficult to distinguish, even on ground photos. The use of cantilevers on arch or suspension bridges can lead to unusual designs, such as the Wichert truss. Placing these hybrid designs into conventional classifications can be difficult.

Figure 36: Diagrams illustrating the application of cantilevered spans to various bridge types.

Floating Bridges

Floating bridges are most commonly used as temporary structures to support military operations. They are the fastest and most economical form of expedient river crossing available for large rivers. Under special circumstances, they are also used as permanent structures to cross large water bodies. Most float bridges are constructed to support roads. However, float bridges supporting single and even double-track railroads have been constructed.

A floating bridge has no substructural supports between the embankments. The floor system rests directly on a series of **floats** or **pontoons**. The flotation device used can be empty steel drums tied together, inflatable rafts, portable military pontoons, small boats upon which the floor system rests, or large, permanent, multichambered pontoons of reinforced concrete.

Tactical military and temporary float bridges are single-lane structures. If another lane of traffic is needed, a second set of floats must be constructed. Permanent float bridges use larger pontoons capable of supporting two or more lanes.

Figure 37: 1) Components of a military style float bridge. 2) Common types of floats and bridge decks.

Float bridges can only be used where strong currents are absent. Even low to moderate currents can require additional anchoring and bracing of the pontoons. On water bodies where the water level fluctuates, the spans linking the shore to the first floating section must be hinged to maintain the connection as the bridge rises or falls.

Float bridges are identified by the low elevation of the bridge deck, no more than one or two meters above the water's surface. There will be very little shadow visible, even at a low sun angle. The floats or pontoons are often visible, protruding out from beneath the floor system.

Prepared Float Bridge Sites: In areas where military conflicts are, or were, anticipated, such as in Germany and Korea, special sites may be prepared to allow the rapid construction of a tactical float bridge. Bearing a close resemblance to a ford, a prepared float bridge site has roads leading to a prepared ramp into the river. However, at these locations, the depth of the water precludes fording. These sites are built mostly for tactical military uses, as backups to provide vital river crossings in case bridges are destroyed by enemy activity.

Movable Spans

Bridges across navigable waterways must allow for passage of vessels under the bridge. Whenever possible, bridges are constructed so at least one span sits high enough to allow ships and boats to pass underneath. However, construction of a span with sufficient underbridge clearance may not be physically or economically feasible. The alternative is to construct a span which can be moved out of the way to allow the marine traffic to pass. Movable spans are more common on older bridges. Currently, the increased cost of the higher spans is justified by the need to keep traffic moving without interruptions.

The most suitable structural form for a movable span is a truss. It provides strength and rigidity, but is still light enough to allow the span to be lifted or swung out of the way. For short spans, girder construction can be used.

There are three common types of movable spans, **lift**, **swing** and **bascule**. These three types are easily distinguished from each other and from stationary spans. The recognition features of a moveable span are:

- The presence of a bridge with low underbridge clearance on a waterway that carries shipping.
- Traffic backed up on either side of the bridge.
- The moveable span in an open position.

Lift Bridges

A lift bridge has two towers, one at each end of the movable span. When the bridge opens, lifting mechanisms in each tower lift the entire span straight upwards, with the span remaining in a horizontal position. The clearance

Figure 38: Two examples of lift bridges, note the massive towers on both bridges. The bridge on the right has an additional overhead truss which serves to strengthen the towers.

provided in the open position is limited by the height to which the span can be raised. The two massive towers readily identify this as a lift span, and the large pulley wheels are often visible. Through type trusses are the usual structural type. Occasionally, the two towers may be braced together at the top by an additional truss.

Swing Bridges

A swing bridge, the most common type of movable span, pivots the span in a horizontal direction. When open, the span is perpendicular to its normal position, and the ends of the span rest on special piers set in the watercourse. The span is, by necessity, cantilevered. The truss shape may be a traditional cantilever or a bowstring. The span may pivot at its center (symmetrical), at an off-center point (asymmetrical) or at one end (end pivot). In order to provide a wider opening, two adjacent swing spans may be used (double-opening type). This is especially true of end pivot bridges. The advantage of a swing span is that it provides unlimited vertical clearance when open.

Swing bridges can be identified by the presence of the supporting piers placed perpendicular to the bridge, as well as navigation channel markers and fenders around the piers. If the moveable span is adjacent to the shoreline, a portion of the shore may be cut out to allow the span to swing around. Through type trusses are the usual structural type.

Bascule Bridges

On a bascule bridge, one end of the span is lifted upwards, tilting the span towards the shore. Bascule bridges may be single opening, or double opening, with opposing tilting sections. The opposing bascules act as two cantilevers locked together when in the down position, since an intermediate support cannot be used. They may be through or deck truss structures, or lighter deck type beam spans. Bascule bridges also have unlimited vertical clearance when open.

A large counterweight is needed to allow the span to be tilted. The counterweight may be above or below the bridge deck, or may be concealed within the

P

5

Figure 39: Top: Recognition factors for swing bridges. Bottom: Several varieties of swing bridges. Note the cantilevered structure of the spans.

pier. The span usually pivots open, but on a rolling lift bascule bridge, it actually rolls back onto its toothed end quadrant, which meshes with a rack on the bank. Bascule bridges can be identified by their presence on a navigable waterway, the counterweights on the shoreward ends, the small control building usually present, the signals or drop gates which stop traffic when the bridge is open, and the lack of lift towers or support piers.

Figure 40: Six of the many possible variations on a bascule bridge

Other Moving Spans

Other configurations of movable spans are relatively rare. A sliding span is retracted horizontally under or beside the supporting structure. A sinking span (existence reported only in Iraq) drops below the water surface to allow boats to pass over it. Other configurations may be encountered. The analyst should be alert to the presence of a moveable span whenever a low bridge crosses a navigable waterway.

Figure 41: A sliding span bridge, in place, and retracted

Unusual Bridges

The last century was a time of extensive building of roads and railways. Bridges were needed to cross larger gaps and carry heavier loads. These new demands led to different engineering solutions. They are usually variations or combinations of the main bridge types discussed above. These bridges are often difficult to fit into classification schemes.

One unusual bridge type is the transporter bridge, which functions much like a bridge crane. A platform suspended from an overhead truss ferries vehicles across the river. (*The continued existence of transporter bridges has not been verified.*)

Figure 42: Transporter bridge (Ferry bridge)

A Wichert truss is a continuous span cantilever truss on which the main span forms a semi-through arch. The deck is suspended below the arch.

Figure 43: A Wichert truss bridge

Other configurations that may be encountered are limited only by the imagination of the engineers and designers. Other features, such as conveyors, may strongly resemble a bridge. A thorough knowledge of bridge structures is required in order to properly identify and describe these features.

Bridge Functions

Identification of a bridge's structural type and the identification of its function are two separate problems. Common engineering principles and practices are used to construct all bridges and bridge-like structures. The best way to identify the function of a bridge is to identify the transportation feature leading up to the bridge. Nevertheless, there are some characteristics that may be visible.

Highway Bridges

There is almost always a distinct contrast between the materials used on the bridge and on the bridge approaches. This will appear as a sharp line perpendicular (except on skew bridges) to the centerline of the bridge. In addition, the roadway usually maintains its width across the bridge, especially on major routes.

Railroad Bridges

Railroad bridges fall into two categories, those with solid decks and those with open decks. A solid deck bridge carries the ballasted track across the gap. These resemble highway bridges in that they maintain the width of the permanent way across the bridge. An open deck bridge has the rails fastened to the floor system of the bridge, and the space between the rails and supports is open. These bridges appear to be very narrow in comparison to the travelled way of the rail line.

Aqueducts and Canal Bridges

Aqueducts are man-made structures that carry water from a distant source to the place it is utilized. The term aqueduct is also used for a bridge that carries a waterway over an obstacle. Canals are man-made structures designed for the use of ships and barges. Irrigation ditches carry water to crop land. All three types of structures may have to cross obstacles to reach their destination.

Some DMA product specifications define the terms aqueduct, canal and ditch differently. Refer to the appropriate specifications to verify the usage of these terms.

The majority of these structures are masonry arch bridges. The majority of canals were built before steel and reinforced concrete were widely used. Recent construction of structures to carry water emphasize the use of pipelines, so the more modern types of structures are less common.

The most distinctive feature of these bridges is the water course which they carry. In hilly or mountainous terrain, aqueducts are often routed through tunnels and across bridges to maintain the downhill grade from source to destination.

There are several other types of structures designed to carry water for short distances for various purposes. These include flumes, penstocks, and elevated pipelines. These may be confused with aqueduct and canal bridges, but closer examination will reveal that the source and destination are close together.

Pipeline Bridges

When pipelines cross areas of high relief, it is frequently more economical to carry the pipeline across a gap, rather than following the ground's surface. Various types of bridging structures can be used, but most are less substantial than other bridge types. Suspension type and steel truss platforms are the most common.

Again, the key to their identification is the pipeline approaching the bridge. Underground pipelines will often be exposed only where they bridge gaps. The absence of any visible transportation features leading to a bridge structure of light construction also implies that this is a pipeline bridge.

Multi-purpose Bridges

The most common multiple use of a bridge structure is the addition of a pipeline (or aqueduct) to an existing road or railroad bridge. Pipelines may be carried alongside or underneath the bridge. Unless the pipeline is quite large, or the pipeline leading up to the bridge is visible, it may not be possible to detect the presence of the pipeline from imagery alone. Older aqueduct bridges, in particular, carried a road on a level above the aqueduct.

Another common combination is the double-deck road and railroad bridge. In some cases, it is economical to build only one bridge to carry both the highway and railroad over an obstacle, with each being carried on a different level. Inspection of the bridge itself, even with a good shadow, may not reveal the existence of the lower deck. Examination of the approaches to the bridge will reveal the convergence of the highway and railroad at the bridge entrance. The analyst must be careful to avoid confusing this with a double-deck highway bridge, where traffic going in each direction is carried on a different level.

As mentioned above, unusual situations lead to unique bridge designs, and the analyst must be alert to the possibility of non-standard features. Familiarity with the geographical area, bridge types and lines of communication, combined with ancillary sources and imagery are required to properly identify and describe the bridges in an assigned area.

Figure 44: The approach to a double-deck bridge (railroad over highway).

Other Transportation Features

A number of other features are associated with transportation routes. These are mostly concerned with carrying the route past obstacles or through difficult terrain. Cuts and fills, causeways, culverts, galleries, tunnels, snowsheds, rocksheds, and ferries will be discussed in this section. These features are most commonly associated with roads and railroads, less commonly with canals, and rarely with pipelines.

Cuts and Fills

In order to allow traffic to move at higher speeds, the transportation route must have relatively low grades and good alignment with broad curves. This is important for major highways, critical for railroads, and essential for canals. In areas of level terrain this is not a problem, but as the relief becomes greater, it becomes more and more difficult to meet the grade and alignment criteria for these routes

The most common method for meeting these grade and alignment criteria is through the use of cuts and fills. A cut is an excavation of the ground surface, while a fill is an area along the route built up by addition of rock and soil. Both are designed to allow passage of a transportation route at an even grade. The term cut is also applied to the edges of excavations made for other purposes. Fill is sometimes used to describe an area which has been built up for construction, but these areas are not mapped as fills. Levees, embankments and berms are similar to fills, but their primary purpose is not to support a route.

Figure 1: A road cut through a hill. Note that the left side of the cut is in shadow, as compared to the road fill in Figure 2.

Cuts and fills are commonly found together along a transportation route, and the material removed from the cuts is used to construct the fills. When the route is perpendicular to the slope, cuts and fills will alternate as the route goes over hills and across valleys. Where the road is parallel to steeper slopes, a cut may be present on the uphill side, while a fill supports the road on the downhill side.

Cuts and fills are more common along railroads and major highways, where low gradients and good alignment are necessary. They are less common along secondary highways, and are infrequently used on minor roads.

Note: The rules for delineation of cuts and fills vary with the product being compiled. Consult the appropriate product specification(s) for inclusion conditions and delineation instructions for cuts and fills.

Cuts and fills are long, narrow features that follow the transportation feature that they support. Thus they tend to be straight or gently curved in plan view. The size of the cuts and fills will vary with the relief of the terrain that the transportation feature crosses.

Figure 2: A road fill. The shadowed side is on the right compared to the cut on Figure 1, with the same sun angle.

The length can vary from a few meters to hundreds of meters. Fills are generally low structures, rarely exceeding ten to twenty meters in height. Cuts can be much deeper, but rarely exceed 75 meters. Beyond a certain height or depth, construction of bridges and tunnels is usually more economical.

The side slopes on fills will be even to gently concave, and rarely exceed 60% because of soil slope stability problems. Shallow cuts through soil or unconsolidated materials will also have gentle, even side slopes, while deeper cuts will often be terraced. Cuts made through rock can have nearly vertical slopes and are usually terraced to lessen the danger of falling rock. Cuts, and less commonly fills, may have diversionary drainage ditches to channel runoff away from the road and prevent erosion.

Cuts and fills appear as narrow bands alongside and parallel to the transportation route. If recently constructed, they will show the tone of the local rock and soil, which normally appears lighter than the surrounding terrain. Some areas, however, are underlain by soil and/or rock of very dark color.

Cuts through rock will have a rougher texture and steeper slope, and will remain devoid of vegetation for much longer than those through soil. Older cuts and fills gradually become covered with vegetation, and will take on the tonal and textural characteristics of the local vegetation. Eventually, the cuts and fills may become so overgrown that they are difficult to distinguish from the natural ground surface.

Because of the relatively shallow side slopes, shadows are not obvious, except on steep cuts through rocky areas. Slopes facing the sun will be lighter in tone than slopes facing away from the sun. Where the relief is slight, or on monoscopic images, cuts and fills can be distinguished by noting the location of the shadowed side in relation to the sun angle.

Figure 3: A road running parallel to the terrain. A fill is present on the downhill (right) side, and on the left, the roadway is locally cut into the hillside.

Causeways

A causeway is a fill built across a low-lying wet area or across a shallow body of water. In these areas, the cost of hauling in the necessary rock and earth is less than that of building long bridges or elevated roadways. Causeways are built of rock, gravel and/or soil, whichever material is locally available. Where erosion by waves or current is a problem, the sides may be faced with large rocks or with concrete.

The causeway will be built just high enough to insure that the transportation route will remain passable at all times. Tides, seasonal rainfall and flooding potential, all effect the height of the structure. In some wetland areas, where causeways several kilometers in length are needed, they may be locally widened to accommodate other facilities.

Causeways are identical in appearance to fills. They are even easier to spot because of the contrast between the dry materials comprising the causeway and the water or wetlands being crossed. Bridges may occur along the causeway, and culverts are common.

Figure 4: A causeway across a body of water

Culverts

Culverts are used to carry water past a transportation route and prevent erosion of the route's foundation. The water could be from an existing drainage feature such as a stream, or it could be from drainage ditches constructed alongside the route itself. There may be a perennial flow of water through the culvert, or it may only carry runoff after periods of rain.

A culvert can be a single pipe, a series of pipes, or a box-like structure. It extends underneath the route and is open at both ends. The diameter of the culvert can range from less than one half meter to five meters or greater, depending on the amount of water it is expected to handle. It can be round, oval or rectangular in cross section. In order to minimize erosion, the culvert will extend out beyond the route's foundation, or headwalls may be added. In some cases, the area around the culvert may be faced with stone or rubble.

A layer of fill material is placed over the culvert in order to distribute the load from the route, so that the weight does not collapse the culvert. **Box culverts** are large, rectangular structures of reinforced concrete, and may be strong enough to bear the load without overhead fill. These "load-bearing" box culverts can be easily mistaken for small slab bridges. The difference is that box culverts have a concrete "floor" while bridges are underlain with the natural stream bed materials. However, the floor of the culvert may be covered by water or gravel.

Figure 5: Two examples of culverts. The left example has stone headwalls to protect the road from erosion. In both cases, the intersection of the ditch or stream with the roadways indicates the presence of a culvert.

Figure 6: This culvert consists of a set of three conduits. A single conduit of equal capacity would have to be much stronger to support the weight of the road.

Figure 7: A load-bearing box culvert. Note: On some DMA products, large load-bearing box culverts are treated as bridges.

Most culverts are fairly small and difficult to see, except on very large scale imagery. Vegetation may be dense along the water course, further obscuring the view of the culvert. The best clue to the existence of a culvert is the presence of a stream or drainage ditch crossing under the route where there is no bridge present. For larger culverts, the round, oval or rectangular shape of the opening, and the shadow within, may be visible.

Note: The inclusion rules for culverts vary among DMA products. For most, only the larger culverts need to be delineated. Consult the appropriate product specifications for instructions on the delineation and description of culverts.

Tunnels

A tunnel is an excavation through a hill or mountain to allow passage of a transportation route. They are normally associated with roads and railroads, but are occasionally found along canals and aqueducts. Tunnels are also used to carry roads and railroads under rivers and other bodies of water. Since tunnels are expensive to build, they will rarely be found on minor roads.

Tunnels range in length from a few tens of meters to several kilometers in length. The tunnel itself is underground, and is not visible on aerial photography. The entrance/exit (portal) to the tunnel and the transportation route leading up to it are the keys to its existence and location. The portals are normally constructed of masonry or concrete, and typically have a rounded or arched shape for strength and stability. This structure stabilizes the entrance to the tunnel and prevents material from falling on the route. The interior (bore) may be lined with masonry or concrete, or left as natural rock if the rock is stable.

The disappearance and reappearance of a transportation route on either side of an obstacle, such as a mountain or river, indicates the presence of a tunnel. A closer examination of the point of disappearance reveals the light tones and geo-

metric shape of the portal. Depending on the orientation of the portal in relation to the sun angle and viewing angle, the shadow may or may not be visible. There will be a cut of varying length just before the portal. Often there will be a turnout prior to the tunnel entrance and a device spanning the road at maximum tunnel height to prevent passage of over height vehicles. On longer tunnels, ventilation fans may be present at the portals or along the length of the tunnel.

The route followed by the tunnel is, of course, hidden from view. For shorter tunnels this can be approximated by connecting the portals with a straight or gently curved line. For longer tunnels, tracing the route may not be possible without other source materials. Ventilation fans placed along the tunnel may be visible.

Note: The symbolization and description of tunnels will vary among different DMA products. Consult the appropriate specifications when delineating this feature.

Tunnels may be confused with underground storage facilities, and the difference is not always apparent. The feature must be analyzed in relation to the regional transportation network. Tunnels will always have at least two portals, an entrance and exit. On rare occasions the route may branch inside the tunnel, and a third portal would be present. Examination of the transportation network will reveal that the route passing through the tunnel is a part of this network. Underground storage facilities can have from one to several entrances. The routes entering the portals will be a branching series of "dead-ends" and the portals will be relatively close together. In addition, there will usually be some above-ground facilities in the area.

Figure 8: Railroad and highway tunnel portals

Galleries, Snowsheds and Rocksheds

In mountainous areas, special precautions must be taken to prevent damage to or blockage of roads and railroads due to avalanches and rock slides. On steeper slopes, accumulations of snow or rock debris are unstable, and can break loose, showering snow, ice or rock onto the lower slopes. For this reason, special structures are built along roads and railroads that pass through these regions. They are located along the steepest slopes, where avalanches or rock slides are most common.

A **gallery** is formed when a road or railroad is cut into a very steep hillside. If the rock is stable enough, an overhang of rock may be left over the road or railroad. This overhang protects the road from falling rock, debris or snow. The overhang may be stabilized by the placement of supports along the outside edge of the gallery. Galleries may be difficult to see on vertical imagery, especially if the look angle creates a terrain masking effect. If the look angle is properly oriented, the shadow of the overhang should be readily visible.

Figure 9: A gallery cut into the side of a steep slope

Snowsheds and **rocksheds** are special, reinforced structures built at points along the route where avalanches or rock slides are common. They are usually built of reinforced concrete and/or masonry, though some snowsheds are built of heavy timbers. The massive construction of these features and their location along steep slopes where landslide or avalanche scars may be visible are the keys to their identification. Heavy walls are often erected above the structure to channel the snow or rock across the section protected by the snowshed or rockshed.

Figure 10: This snowshed was built to protect the road from drifting snow.

Snowsheds and rocksheds are very similar in appearance, as they are similar in function. If the structure is located at a higher elevation in the mountains, where large accumulations of snow are normal, it can be called a snowshed. Those at lower elevations, or in the valleys between the mountains can be called rocksheds. This classification is somewhat arbitrary, as the structures will protect the route equally from both types of hazard. Snowsheds are sometimes built along roads and railroads in areas where drifting snow would otherwise close the route.

To identify snowsheds and rocksheds, look for points along and at the base of steep slopes where the road or railroad disappears into a structure that seems to be built into the slope. The structure will have an angular configuration, will

Figure 11: Rockshed (left) and snowshed (right). Note the similarity in appearance.

be partially open on the downhill side, and will have wing walls upslope to direct debris and snow over the structure. Landslide or avalanche scars will normally be visible on the slope above the structure. Concrete structures will be very light in tone, and may be difficult to spot against a snowy background. Masonry, native stone or timber structures will be darker. In all cases, look for the angular shadows cast by the structure and the wing walls, and the disappearance and reappearance of the route on either side.

Ferries

Occasionally, a road or railroad will cross a water body where it is impractical to build a bridge or other crossing device. Either the traffic is too light to justify the cost, or the water is too wide or too deep. In these cases, **ferries** can be used to carry traffic across the water body. Ferries also carry traffic out to islands not connected to the mainland by roads. Ferries vary in size from small pedestrian barges, to large ships capable of handling trains, cars, and/or hundreds of passengers. Depending on the volume of traffic, the facilities for loading and unloading can vary from a ramp leading down to the water's edge, to a well-developed **ferry slip**, complete with terminal buildings and passenger waiting areas.

Ferries across narrow water gaps, such as rivers, are easy to spot, as the road or railroad stops abruptly at the water's edge and continues on the other side. Except for the presence of the ferry, the crossing may resemble a ford or a prepared float bridge site. When the ferry crossing is on a larger body of water, and the opposite terminal is farther away, the ferry slip may be confused with facilities used for other shipping activities.

Dumb ferries

Most large ferries are self-propelled, and operate independently like other ships. A **dumb ferry** is a small (from 2 to 5 meters (8 to 15 feet) wide by 6 to 12 meters (20 to 40 feet) long), rectangular barge, without a motorized propulsion system. It has no superstructure or holds, and safety rails are normally present around the sides. It can handle only passengers or a few small vehicles, which will be visible on the open deck of the ferry.

Figure 12: A cable-guided dumb ferry

Dumb ferries may rely on tug boats for motive power, while others are propelled via poles or currents. On narrow rivers that have little or no marine traffic, a dumb ferry may operate via a set of cables stretched across the river. The opposing slips are simple, rectangular in shape, and may or may not have a ramp (the ramp may be on the ferry). The slips are connected by a set of parallel cables to which the ferry is attached. The most primitive ferries are moved by poling, currents, or by people pulling the barge along the stationary cable. Some cable ferries use a winch on board the ferry to pull themselves along. Others are attached to cables which are pulled by winches on either side of the river. The winch gear and pulley system will be visible next to the slip, though it may be housed in a small building.

Powered ferries

Powered ferries fall into two categories, paddle-wheel or propeller driven craft. Both have clear decks fore and aft of a raised center section. The main difference between the two is the abrupt widening of the beam to accommodate the paddle wheels. Both will have stacks in the center of the vessel, and rectangular pilot houses facing in each direction. Powered ferries range from 4.5 to 18 meters (15 to 60 feet) in width and 12 to 60 meters (40 to 200 feet) in length.

Passenger ferries may load from the sides or from the end. Vehicular and rail ferries load from one end and unload off the opposite end. Side-loading passenger ferries, particularly larger ones, resemble other ships, and have a pointed bow and rounded stern, while end-loading ferries are more rectangular, tapering slightly toward the squared-off ends.

Figure 13: Examples of several types of powered ferries

Ferry slips

Small ferries can operate from a paved or unpaved ramp leading down to the water's edge, or a small, rectangular dock. Larger ferries can have a large dock, with a terminal building, and waiting areas for passengers and vehicles. For road and railroad ferries, the road or railroad track will extend right to the edge of the dock. A gate or cross bar near the edge of the dock will be visible. The dock may extend out into the water to insure a sufficient depth of water for the ferry. The slip will be wide enough to accommodate the vehicles being loaded onto the ferry.

Figure 14: A railroad ferry slip

The alignment of the ferry with the road or railroad track from which the vehicles are being loaded is critical. Small, wing-like structures may extend out from the end of the slip to help guide the ferry into the proper alignment at the dock.

Ferry slips can be distinguished from other port facilities by the road or railroad extending out to the edge of the dock, the presence of a ferryboat at the slip, or the presence of passenger or vehicle waiting areas at the slip. If the water gap is narrow, the slip at the opposite side would also be visible.

Ferry Routes

The ferry's route may be anywhere from less than a hundred meters to many kilometers in length. The route is not visible but can be inferred by the placement of the slips and ferry traffic along the route. For longer routes, the route must be obtained from an ancillary source.

Figure 15: A vehicular ferry slip

Airfields

Air transportation differs from the other transportation systems in that there are no physical structures associated with air travel routes, although preferred routes can be plotted on maps, especially for commercial air traffic. Therefore, this chapter will cover only the terminal facilities, that is, the airfields themselves. The task of identifying and describing airfields is made somewhat simpler by the fact that *all airfields, from the simplest dirt strip to the most complex civil or military air facility generally look alike, and provide the same services, using similar equipment, worldwide.*

Before the Wright brother's motor driven plane flew a distance of 850 feet in December 1903, two basic ground support problems had to be solved. A place was needed to store the aircraft for maintenance and protection from the environment, and a cleared and level piece of ground was needed to build a take-off and landing area. The solution to these basic problems provided the United States with its first airfield and associated support facilities. Although there are more types of aircraft now, and aircraft designs have changed since 1903, the fundamental airfield ground support problems have not. This chapter will explain and illustrate these problems and their solutions affect the appearance of airfields and their facilities.

This chapter only discusses the basic aspects of airfields, those necessary for the accurate depiction of airfields and associated features on standard maps and charts. A detailed discussion of airfields and associated facilities is contained in Module 6, Airfield Imagery Interpretation.

Airfield Definition

An airfield is an area specifically designed and constructed for landing, accommodating, and launching military or civilian aircraft. Synonyms for the term airfield include: airdrome, airport, airstrip, air base, air park, heliport, helipad, seaplane station, and landing ground. For purposes of this discussion the term "airfield" is used in the broadest sense to designate all facilities, regardless of complexity or size designed for use by aircraft.

Airfield installations are those facilities that support the continued operation, maintenance, and repair of aircraft using the field. These installations consist of runways, taxiways, parking facilities, hangars, fueling and fuel storage facilities, navigational facilities, weapon storage areas, and passenger or cargo handling areas. To be categorized as an airfield facility the site must have a minimum of one visually identifiable runway.

Military and Civilian Airfields

Civilian and military airfields have several identifiable differences that reveal the intended use of the airfield. Civilian airfields are usually located near the city that they serve. Airfields found nearby or within heavily populated areas are usually classified as civilian or joint use civil/military airfields.

Military airfields normally occupy more land area than civil airfields because of the large amount of housing, storage, and related services that are associated with military operations. Military airfields are usually located away from large population centers. The presence of barracks areas for personnel, military combat aircraft, munitions storage, parade grounds, and a generalized military appearance leaves no question that the airfield is solely used for military air operations. The presence of military fighter, bomber and transport aircraft parked at the

Figure 1: Military Aircraft Facility

airfield is the best means of confirming that an airfield is used for military air operations. It is not uncommon to see several rows of the same type and model of aircraft parked at a military airfield. In the past, the number and size of aircraft hangars at an airfield indicated the primary use of the airfield, however, that generality is no longer reliable.

Heliports include helipads and other cleared areas that are marked and specially designated to serve helicopter take off and landings. The main characteristics of a heliport are the presence of helicopters parked on separate pads, a short runway or no runway, and helicopter specific landing zone markings on the pads and aprons. The runway at a heliport is usually not paved, it is short and wide when compared to the proportions

Figure 2: Military Heliport

Figure 4: Joint Military/Civilian Air Facility

Joint military and civilian airfields are commonly found near large metropolitan areas. For economic reasons, joint use airfields are quite common throughout the world, they serve passenger, cargo and military aircraft operations and save money by sharing the operating expenses for the runway.

Highway airstrips are common throughout the world. Some sections of the interstate highway system have been modified to serve as runways during wartime or emergency conditions. Portions of the highway that are suitable for use as landing surfaces offer long stretches of unobstructed highway (no overpasses or overhead powerline crossings), a good tactical location, and a level surface. For the roadway to become the runway, the road is paved and reinforced to sustain repeated aircraft landings, and aircraft turn around aprons are added to each end of the selected roadway. During periods of normal use, the turn around aprons serve as automobile rest stops and have the same appearance on overhead imagery.

Figure 5: Highway Airstrip

Id Location

The most advantageous location for an airfield is in an area free of natural and cultural impediments to operations. An elevated site for airfield construction is preferred because of the absence of terrain obstructions and the likelihood of having more favorable local weather.

Whenever possible, airfields are constructed at locations away from river bottoms and flood plains, to avoid flooding and ground fog problems. Lower elevation areas are sometimes selected for airfield construction because the cost associated with acquiring the property is usually quite low. In heavily forested or jungle areas, low land along rivers is often the easiest to level and clear.

Prevailing winds at the proposed building site are evaluated in order to select a orientation that will receive the least exposure to hazardous crosswinds. A orientation parallel to the prevailing wind direction is selected, thus avoiding dangerous crosswinds at the airfield. Another consideration of site

Whenever possible, airfields are constructed at locations away from river bottoms and flood plains, to avoid flooding and ground fog problems. Lower elevation sites are sometimes selected for airfield construction because the cost associated with acquiring the property is usually quite low. In heavily forested or jungle areas, low land along rivers is often the easiest to level and clear.

Prevailing winds at the proposed building site are evaluated in order to select a runway orientation that will receive the least exposure to hazardous crosswinds. A runway orientation parallel to the prevailing wind direction is selected, thus minimizing dangerous crosswinds at the airfield. Another consideration of site

selection is extendibility. Natural or man made obstructions may exist that would limit the distance a runway can be extended. Water areas, built-up areas, canyons, hills or mountains, are all examples of obstructions that would impose a significant increase to the construction cost of increasing the length of a runway. Under normal conditions, the expenses involved in bridging the natural obstructions influence the decision to extend a runway more often than do civil engineering limitations.

Runways

The main distinguishing characteristic of an airfield is the presence of one or more visible runways. A single runway is the only element necessary for an area to be identified as an airfield facility, no other components need to be present. The presence of an aircraft parked on the ground (such as those found at static aircraft displays) does not constitute an airfield.

The length, width, condition, and type of landing surface material have a direct impact on the type and amount of aircraft traffic a facility can bear. These characteristics of the runway are all aerial photo discernible traits and can be correctly identified by a trained imagery analyst.

Airfields can have single or multiple runways to accommodate various traffic loads and changing wind conditions. The most common multi-runway patterns are parallel, V-shaped, T shaped and X-shaped.

Landing Surface Types

Perhaps the most difficult of all the runway characteristics to determine on imagery is the landing surface type. Runway surfaces are divided into **natural**, **prepared natural**, **semi-rigid**, **rigid**, and **prefabricated** landing surfaces. The load bearing capacity of each surface material varies, as does the wheel load weight of the aircraft and the anticipated amount of air traffic at the airfield. Thus, the length of the runway is not the single most important factor in determining an airfield's operational capacity.

Natural Surfaces

Natural surface runways are paved with the natural soil and vegetation that covers the earth at that location. These runways require minimal surface preparations (grass mowing) to ready them for aircraft landing and take off operations.

Natural surface runways made of **sod**, **grass**, and **turf** are sometimes delineated by day markers placed along the sides of the runway and at the corners of each runway end. During wet seasons, natural surface runways become soft and are easily imprinted with aircraft tire tracks. During drier than normal conditions, surface vegetation on the runway erodes and takes on a lighter tone due to repeated daily use and drought.

Figure 6: A grass runway used primarily for gliders and their towplanes. Note the similarity in tone between the runway and surrounding areas.

The edges of natural surface runways are irregular and their tone varies from dark to light gray depending on the season of the year and the type of soil present or vegetation growing there. When the tone of the runway and surrounding surface vegetation are similar or exactly alike, you can be certain that you are looking at a grass, sod or turf covered runway. By finding a cultivated field and comparing the tone of the exposed soil to that on the runway, you can confirm that the surface is made of soil or sand and not grass.

The texture of a grass runway is usually smoother than the surrounding vegetation when the runway surface has been mowed and maintained.

Natural surface runways are sometimes only usable during the dry season or when the ground is frozen. Multi-seasonal use of natural surface runways depends upon adequate soil drainage, the weight of the aircraft using the runway, and the presence and duration of ground frost.

Natural surface runways are found in all five length categories. Many modern cargo and passenger aircraft are designed to operate on diverse landing surfaces, including grass and sod, military transport aircraft routinely land on these surfaces.

Natural surface runways are low contrast features and are difficult to detect because they are made from the same material as the surrounding natural surface cover.

Natural surface runways are low contrast features and are difficult to detect because they are made from the same material as the surrounding natural surface cover.

Prepared Natural Surfaces

Natural surfaces used for runways can be improved by modifying the surface through grading, leveling, draining and conditioning the soil prior to use for air operations. Surface materials that are commonly used for airfield construction are: graded earth, sand, clay, coral, laterite, gravel, crushed stone, and soil/cement mixtures.

Graded Earth: Prepared natural surface runways have a different appearance than natural surface runways. Various surface preparation techniques initially require the upper layer of vegetation or surface material to be scraped off the runway site, thus leaving freshly exposed subsoil to become the base for the new runway surface. The exposed subsoil will exhibit the same tone as the exposed subsoil found on local

farms and unimproved roads. When natural soils at a site have properties that do not provide adequate drainage, or that compaction will not improve, they can be corrected by the addition of sand, clay, calcium chloride, sodium chloride or bituminous materials, any of which can alter the tone of the runway, making it differ from the surrounding soil. Earthen runways are generally short and narrow, and serve small aircraft only. Military forces use earthen airstrips during wartime and military exercises for the delivery of cargo to forward areas. Earthen strips deteriorate under heavy use, thus it can be assumed that a facility with an earthen strip is used infrequently. Earthen airstrips for military use are much larger than the usual graded earth airstrip.

Laterite: Laterite is a red, residual soil containing large amounts of aluminum and ferric hydroxides. It is formed by the decomposition of many kinds of rocks, and is only found in well drained tropical rain forests. Runways made of laterite soils are most commonly found in East Africa and Southeast Asia (Laos, Viet Nam, Cambodia). Laterite runways are usually short (1200ft) and narrow (30-50ft), and can only accommodate small single or dual engine aircraft. A laterite runway generally has a light or mottled tone that is somewhat lighter than the surrounding soil. Airstrips made of laterite may be smooth in texture or imprinted by grader marks. These runways have irregular shoulders and indistinct corners on the runway ends.

Gravel Surfaces: Gravel is low cost surface treatment that is sometimes used for runway construction. On runways with gravel surfaces, large particles of loose aggregate can be kicked up by aircraft tires and exhaust, thereby inflicting damage to the aircraft and engines. To reduce the possibility of damage to aircraft, gravel consisting of small aggregates is mixed with binders and compacted to create a safe runway surface. When gravel, crushed stone, or a soil cement mix is deposited over the subsoil, the tonal difference between the area covered and the exposed subsoil is usually noticeably different and easily detected. Typically, these surfaces are light-toned due to the surface application of calcium chloride for moisture retention and dust suppression.

Coral Surface: Coral surfaced runways are found mostly in the Caribbean, Indian, and Pacific oceans. Coral runways usually exhibit the same tone as the surrounding earth's surface. With the exception of looking cleaner, (because of sparse ground vegetation and removal of surface irregularities by grading), coral runways look remarkably similar to the rest of the island that they occupy. The similarity in tone is greater for runways located near the beach or coastal area.

The analyst must make certain that the island where the runway is located has a coral substructure, as not all island runways are coral surfaced. Coral is absent from the West coast of continents, and can only exist in areas with an ambient temperature above 68 degrees. It

will only be found in areas within 30 degrees north or south of the equator (except Bermuda). The crushed coral surfaces are graded smooth and level to provide good drainage, and create a consistently smooth surface for take-off and landing.

Sand surface: Sand surfaced runways are found in all size categories, however the majority of them are normally smaller in size. The overall tone of a sand runway is lighter than the surrounding sand and is normally characterized by grader marks and tire tracks. Sand runways are found in desert areas, on islands, and along coastal areas.

Ice and snow: Ice or snow surfaced runways are found in the high latitudes and are commonly temporary features that disappear with the onset of the spring thaw. When made of snow or ice, and located in no thaw zones, they are permanent features and can be found in all length categories. Because ice that is formed over water creates a naturally level and smooth surface that is free of obstructions, many permanent or temporary runways are found on frozen lakes and bays. These runways always have a white tone and smooth texture with some evidence of tracks from landing aircraft. Runway edge lights and/or day markers are often used to delineate the ice/snow runway.

Clay: Clay surfaced runways are virtually indistinguishable from earthen runways on aerial photography. Ancillary sources (soil survey maps) are the best source of information to confirm the presence of a clay runway.

Bedrock: Bedrock runways are found throughout the world and will have the same tone as rock outcroppings in the local area. Bedrock is locally exposed on the surface of the earth and is a very stable surface for landing all sizes of aircraft.

Semi-Rigid Surfaces

Semi-rigid runway surfaces consist of **asphalt, bitumen, or macadam**. All of these surface treatments are relatively permanent and differ mainly in terms of water penetrability, type of materials used in the mix, percentage of bitumen added and surface preparation prior to application. Bitumen is the main binding ingredient in macadam and bitumen type runway surfaces, it is also used with asphalt on asphalt runways.

The American Society for Testing Materials (ASTM) defines bitumen, the binding or cementing agent in bituminous paving materials, as follows:

Bitumen, a mixture of hydrocarbons of natural or pyrogenous (produced by application of heat) origin, or both, frequently accompanied by their non-metallic derivatives, which may be gaseous, liquid, semi-solid or solid and which are completely soluble in carbon disulfide.

Asphalt, a black or dark brown solid or semi-solid cementitious material which gradually liquifies when heated, in which the predominating

constituents are bitumens, all of which occur in the solid or semi-solid form in nature, or are obtained by refining petroleum, or which are combinations of the bitumens mentioned with each other or with petroleum or derivatives thereof.

The primary difference between bitumen and asphalt are:

1. bitumens remain liquid or semisolid at or slightly above normal temperatures, whereas asphalt compounds will remain solid.
2. Asphalt runway surfaces do not permit water penetration, whereas bitumen compound runways do.

Bituminous mixes for paving purposes consist of aggregate and bituminous binding material. These constituents are blended and mixed to give a product which when laid down and compacted will result in a pavement or runway having the desired durability and load bearing capacity. The most important variable in a bituminous paving mix is the quantity of bitumen. If excess bitumen is present, the mix will lack stability and will rut and creep under traffic. A slight excess will result in an oily, slick surface that is dangerous, particularly when wet. The four major bitumen surfaces are: Soil-bitumen, Sand-Bitumen, Oiled earth and Macadam.

Soil-Bitumen: These surfaces are water-resistant, cohesive soil systems that provide medium weight bearing ability for all weather runways. Their surfaces have a very dark tone and are created by mixing soil and bitumen together, then curing and compacting the material. These surfaces are found worldwide and are usually associated with temporary airfields or airfields that do not receive much traffic.

Sand-Bitumen: These surfaces are water resistant systems in which loose beach, dune, pit, or river sands are cemented with bituminous material. This construction differs from soil-bitumen mainly in type of aggregate mixed with the bitumen. This type of surface is commonly found in the desert areas of the Middle East, where large amounts of sand and bitumen are easily and economically acquired. These runways are markedly darker in tone than the surrounding area.

Oiled-Earth: These runways are made water and abrasion resistant by the application of slow or medium curing oils to the graded earth surfaces. This type of treatment will yield a runway that is dark in tone and suitable for light, all weather traffic.

Macadam: This surface pavement for light traffic was named after its inventor, John MacAdam. It consists of a layer of crushed stone that has the voids filled with smaller stones and stone screenings and is compacted and bonded in some way to prevent its displacement. A bituminous material or cement grout may be used as binder. A macadam surface without binders, or with cement grout is light in tone compared to the dark bituminous bonded material.

Asphalt: This type of pavement consists of a refined asphalt that may or may not require the addition of a non-volatile petroleum oil to render it suitable for paving purposes. One source of asphalt is native asphalt lakes, another is derivation from the residue from the fractional distillation of asphaltic base or petroleum. There are various types of asphalt mixtures and processes for creating a pavement of the desired surface roughness and durability.

When viewed on imagery asphalt runways appear to have neat straight edges, are predominantly dark in tone and may have visible (painted) runway markings. The exception to this is found on aged asphalt runways. As time passes the surface becomes lighter due to accumulated dirt and surface wear. Aged runways are frequently re-sealed and appear as dark as freshly laid asphalt.

Figure 7: A weathered asphalt runway, with grass encroachment along the runway edges

Rigid Surfaces

The design of rigid concrete pavements for airports is unique because of the varying wheel loads and operating characteristics of the aircraft using the runways. Throughout the central 70% of its length, the thickness of the runway is thinner than at the approach ends. Taxiway thickness is usually equal to or less than the runway. The reduced thickness of the center runway and taxiways is permissible because at those areas, aircraft are moving, thus the stress on those surfaces is of a short duration. When the aircraft is stationary, surface stress is increased due to heavier static wheel loads and the sustained transmission of motor vibrations to the operating surface. The runway approach ends must be substantially thicker to absorb the tremendous impact they receive from inbound landing aircraft. Tire marks on one or both ends of the runway attest to the beating these areas receive. Due to their infrequent use, paved runway overruns are the same thickness as taxiways or the middle portion of the runway.

Aircraft parking areas, (when paved), are usually made of concrete in order to support the concentrated weight of aircraft over long periods. In addition, concrete will not soften when exposed to high daily temperatures.

Concrete Runways: On optical imagery, concrete runways generally appear light in tone, with neat straight edges, non-rigid shoulders and sometimes visible runway markings and edge lights. Typical concrete runways are poured on site, however in areas of frost heaving, prefabricated cement blocks are brought in and laid down to create a stable yet flexible runway surface.

Concrete runways that have been poured on site have expansion joints built in to them to allow for expansion and contraction due to heating and cooling of the cement surface. Expansion joints extend across the runway from edge to edge and like runway drainage grates, creating dark lines across the runway that are often noticeable on airfield imagery.

Cement Block: Runway surfaces composed of cement blocks (rectangular or octagonal blocks), have dark lines where the blocks are joined and sealed with waterproof asphalt sealers to prevent water penetration and freeze damage. Taxiing and landing on prefabricated cement block surfaces gives passengers and crew the same physical sensation that an automobile receives when driving on a brick paved street.

Figure 8: Concrete runway with markings painted on the surface

Prefabricated Surfaces

Prefabricated surfaces for landing and parking surfaces differ from precast cement slabs in that they are made of thin, lightweight materials and are intended to be used as a temporary surface. Prefabricated surfaces are usually found at temporary military airfields in areas where military exercise or war conditions exist. Prefabricated runways are also found in remote regions (polar or jungle), where scientific research or exploration base camps need a temporary and hasty runway surface. The main function these surfaces serve is to allow engineers to quickly construct a stable and level runway or parking surface over minimally improved airfield sites.

Prefabricated panels are designed to be assembled quickly and handled by a minimum of personnel. They are made of lightweight materials such as aluminum mat or thin steel. Each sheet measures approximately 4 ft. X 10 ft. Pierced steel planking (PSP) sheets are made lighter by perforating each panel with a matrix of uniformly placed 3in. holes across the panel. Both solid and PSP prefab panels are constructed with edges that interlock or weave together, thus enabling easy removal or replacement when needed.

Pierced Steel Planking: Because pierced steel planking is essentially a grid work of holes in a steel panel, grass can easily grow on the exposed earth inside of the holes, this results in a surface appearance that is dark in tone and somewhat textured. When PSP is placed on a newly graded surface or upon sand, the lighter subsoil showing through the panel yields an overall light tone when contrasted against the darker rusty steel panel.

Aluminum Mat: is made of solid panels with an olive drab green painted and textured surface that appears either darker or the same tone as the background that it is laid upon. Aluminum mat and PSP form similar patterns made of fine lines in a grid pattern where the panels join together. When taxiways and parking areas are added to the runway, sawtooth or stepped edges are formed around their outer edges, due to the rectangular shape of each panel that is used to create the area.

Figure 9: Expedient runways of pierced steel planking (left) and aluminum mats (right)

Figure 10: Diagram of an expedient prefabricated membrane runway

Prefabricated Membrane:

Prefabricated membrane is made of vinyl or rubber impregnated fabric and is packaged in rolls that allow it to be rolled into place, easily joined, and anchored around the edges. The main advantages of this type of surface lies in its apparent ease of installation and ability to prevent water from penetrating and softening the soil beneath it.

Prefabricated Membrane surfaces have very little impact or abrasion resistance, and are best used in light wheel load fixed wing aircraft or helicopter operations. Prefabricated membrane is olive drab in color. On imagery it will generally appear to be dark or medium toned, depending on the overall tone of the background it is placed against.

Type of Surface	Description	Tone	Options
Sod	irregular	same as surrounding	day markers
Grass	irregular	mottled light to dark	tire tracks
Turf	irregular	mottled light to dark	tire tracks
Graded Earth	smooth	light to dark subsoil	tire tracks
Sand	irregular	light to medium	sand fence
Gravel	smooth	light to medium	n/a
Coral	smooth	light to white	day markers
Asphalt	regular	dark to medium	markings
Bitumen	regular	dark	n/a
Macadam	regular	dark to light	n/a
Concrete	smooth	lt. gray to white	markings
Prefab panel	grided	mottled med. dark	piles of PSP and panels

Table 1: Summary of characteristics of runway surface types

Runway Length

Runway length is determined before construction by establishing how many, what size, and what type of aircraft will use the airfield. Specific characteristics about the types of aircraft that will be using the runway are vital to the process of runway length calculation.

The amount of runway required for the safe take off and landing of an aircraft is determined by the aircraft design limits and site specific meteorological conditions. Aircraft designers and manufacturers create an index for each aircraft that tells the pilot how much runway is needed to take off and land with a predetermined margin of safety. To produce the index, aircraft engineers analyze the thrust to drag figures of each aircraft, its maximum and minimum load (fuel, passengers, cargo), the annual high/low pressure density of the atmosphere at site. After the data for each aircraft and the atmospheric conditions are considered, the "minimum distance, take off and landing table" is published for that specific aircraft. By obtaining the maximum and minimum runway requirements for each aircraft using the runway, an acceptable runway length is determined.

Five classes of airfields (based on runway length and width) have been established. These five airfield categories have corresponding runway lengths that will accommodate virtually all the types of aircraft that operate in the USA.

Airfield Runway Dimensions

Airfields are classified according to length of delineated runways as shown in the following Table.

Type of Service	Runway Length	Runway Width
Class 5 (personal)	1500-2300 ft.	50 ft.-20 ft.
Class 5 (secondary)	2301-3000 ft.	75 ft.-30 ft.
Class 5 (feeder)	3001-3500 ft.	100 ft.-40 ft.
Class 4 (trunk line)	3501-4200 ft.	150 ft.-50 ft.
Class 4 (express)	4201-5000 ft.	150 ft.-60 ft.
Class 3 (Continental)	5001-5900 ft.	150 ft.-75 ft.
Class 2 (Intercontinental)	5901-7000 ft.	200 ft.-75 ft.
Class 1 (Intercontinental)	7001-8400 ft.	200 ft.-75 ft.

Table 2: Runway classification by length

Runway Safety Measures

An important aspect of runway length is the inclusion of a safety factor. In the event of an aborted take off or a "far beyond threshold" landing, some aircraft are not able to stop rolling before reaching the end of the runway. For safety, many airfields have added **runway overruns** and cleared areas at the runway ends to allow aircraft to safely continue rolling beyond the ends of the runway.

Another safety measure to prevent aircraft from rolling beyond the end of the runway is the **runway barrier net**. This device resembles a tennis net that is activated from the control tower at the pilots request. Normally the net is at or below the surface level of the runway and will look like a dark line across the runway with two black or white boxes on each side. In the stowed position, aircraft can roll over the net without being restrained. When deployed the net is raised above the runway and looks like a tennis net. Two square boxes on each side of the runway contain retractor reels with cabling that absorb the force of the aircraft enabling it to stop. The aircraft rolls into the barrier net, is caught, and stopped before running off the end of the runway. A runway barrier net is usually located on the extreme end(s) of the runway in order to keep aircraft from going beyond the runway overrun.

Figure 11: Runway overrun and barrier net

An **arresting gear** is a type of barrier system device consisting of an elevated cable connected to reels mounted on both sides of the runway. It is used for the purpose of stopping tail hook and non-tailhook equipped aircraft. A cable is stretched across the runway and is caught by the tail hook or landing gear of the inbound aircraft, as the cable is stretched the energy of the aircraft is reduced thus preventing the aircraft from going beyond the overrun. Arresting gear cable systems are usually located just beyond the designated wheel touchdown zone.

Photo Interpretation Training Course

Figure 12: Runway with arresting gear. Note that the arresting cables are located inside of the runway's thresholds, as opposed to the barrier nets which are placed on the overruns.

Runway Markings

Airfield marking systems serve as visual aids to help locate and identify runways, taxiways, and parking areas. They also provide approach heading and glide slope information for inbound aircraft.

The arrangement, size and type of runway markings in the United States is standardized by the Federal Aviation Administration (FAA) and the International Civil Aviation Organization (ICAO). ICAO standards are observed by countries worldwide but are only mandated at international airfields. Nation specific runway marking schemes may be found at non-ICAO airfields. Runway marking requirements are divided into four groups, each related to the severity of the operating conditions and the intended purpose of the airfield. These conditions are defined as follows:

1. **Privately owned non-public access airfields** and primitive bush strips may have daytime markers, (white painted objects arranged in an L shape used to define the corners of the runway), or they may have no runway markings at all.
2. **Basic Visual runway markings** are used for operation during daylight, good visibility weather and (Visual Flight Rule) VFR conditions. These consist of:
 - a) Centerline markings
 - b) Runway designators
 - c) Fixed distance markers on runways greater than 4000 feet.
 - d) Holding position markings and an illuminated visual landing system.

Figure 13: Precision Instrument Runway Markings

Figure 14: VFR (Visual Flight Rules) Runway (Basic Markings)

3. **Non-Precision Instrument Runway Marking** used for aircraft operating under Instrument Flight Rule (IFR) conditions have all of the above markings plus a visual landing system.
4. **Precision Instrument Runway Airfields** accommodate aircraft operating in all types of weather, they have illuminated runway markers, all of the above-mentioned markings, edge stripes, edge lights, landing zone markers, and (non-visual approach) landing systems.

Non Illuminated Runway Markings

The basic function that runway markers provide, is to delineate the usable operational limits of the runway. Just as there are many types of highway signs and roadway markings for automobile drivers, there are also numerous runway markings to identify runway orientation, centerline, threshold, touchdown zones and usability status. For ease of discussion, illuminated and non-illuminated markers will be covered separately.

Day Markers

Associated with natural surface runways, **day markers** are made from stone, semi-buried tires, cement, wood, metal panels or any material that when painted white and arranged in an (L or I) shaped pattern is large enough to be viewed from aloft. Day markers as described, are used to visibly delineate the ends and sides of the runway.

Figure 14: Day Markers with lights made from tires painted white

Runway Designators

Runway heading markers are used to name the runway, indicate the magnetic orientation and identify left/right runway designation on rigid and semi-rigid surface runways. They are white numerals and letters that are large enough to be identified from the air at a distance of one quarter mile in clear weather are applied to the runway ends. These markers also accent the landing and take off area of the airfield.

White numerals are used to depict the magnetic azimuth of the runway to the nearest ten degrees. When portrayed on a runway, azimuth is always depicted by a combination of two digits. For example, a runway orientation that is surveyed at 085° East and 265° West, is marked by rounding the magnetic orientation of the runway up to the nearest ten degrees and then abbreviating it by deleting the last zero. Runway heading marker numerals are then displayed as 09 and 27.

Heading indicator numerals do not identify the north, south, east, or west ends of the runway, they indicate the heading or azimuth that will be read on the aircraft compass if you are approaching the runway from the indicated end. Heading markers indicate the magnetic heading needed to approach and align an aircraft with the runway.

Figure 16: Runway Heading marker and centerline

Figure 17: Runway designators on a three runway airfield

Thus, on an east to west oriented runway, the 09° numerals are applied to the west end of the runway to match the compass heading that an inbound aircraft would have when approaching the runway from this direction.

In order to eliminate confusion when naming runways, a scheme of letters and heading numerals was instituted. At airfields having multiple, parallel runways, left from right differentiation is made by including the relative position of the runway (as viewed from the approach ends), left, center, or right in the heading marker name. Left, right and center runways are separately identified by the placement of a white capital letter (L, R, or C), beneath the respective heading numerals. This is illustrated by the diagram shown as figure 17.

Centerline marking

A runway centerline is applied to rigid and semi-rigid runways to provide the aircraft pilot with a visual reference for finding the runway center during landings, taxiing and take-off. Centerline stripes are commonly depicted on the runway surface as a white 120ft. line broken by 80ft. spaces. The minimum width for the centerline at a basic airfield runway is 1 foot. At Day/Night all weather runways the centerline is 3 feet wide.

Threshold Marking

The runway threshold is the designated end of the runway. Although inbound aircraft can make initial wheel contact with the runway at the threshold, usually the touchdown zone is just beyond the runway end or threshold. Threshold ends of the runway are paved with material that is thick enough to sustain the impact of a landing aircraft.

[illegible]

Figure 19: Threshold markings, heading designator, centerline and edge stripes

A displaced threshold is a portion of the runway located at the ends of the runway that is not intended to be used as a landing zone. Some airfields have displaced thresholds due to the addition of paved overruns. Areas indicated by displaced threshold markings are not strong enough to withstand the impacting wheel load of a landing aircraft. Often, displaced thresholds are added years after a runway was constructed, thus providing an extension to the previous runway for landing roll out, taxiing, or take off. These areas are not strong enough to withstand repeated landings.

Figure 20: Displaced Thresholds

Displaced threshold markings are depicted by a series of two symbols. Beginning as a single row of separate arrow tipped white lines placed along the centerline of the threshold, these markings are terminated by a series of small inverted "V" or chevron shaped symbols extending across the displaced threshold end, and pointing toward the solid line that indicates the beginning of the runway.

Figure 21: An asphalt runway with a displaced threshold

Touchdown Zone Marking

These markings provide the inbound aircraft pilot with a visual target that indicates where to make wheel contact with the runway.

Touchdown zone markers are very similar in appearance to threshold markings. They consist of a series of two groups of white stripes extending inward from each edge of the runway. The primary difference is that the touchdown zone is located just beyond the threshold marker. The surrounding runway pavement at the touchdown zone is usually darkened by tire marks from repeated aircraft landings.

Figure 22: Touchdown zone and fixed distance markers

Edge Stripes

Edge stripes are solid white lines that are used to mark the point where the outer edge of the runway surface meets the shoulder. The visual reference that they provide for the pilot is the same cue that highway edge lines provide for the motorist.

Fixed Distance Markers

Fixed Distance Markers have a similar appearance and function as touchdown zone markers. This marker is composed of two large solid white rectangles on each side of the centerline and located 1000 feet from the threshold. The fixed distance marker is used as a visual reference for landing turbo-jet aircraft on precision and non-precision runways.

Stopway Markings

Stopways are paved areas beyond the end of the runway that are suitable for use during an aborted take off or whenever an aircraft unexpectedly requires a stopping distance beyond the normal limits of the usable runway. Stopways are marked with a repeated series of large, chevron shaped white lines, painted across the width of the stopway, and pointing toward the runway end.

Closed Runway

A runway that is unusable, hazardous or no longer used is marked by white "X" shaped markings. The markers are painted along the runway center at even intervals along the entire length of the closed runway. The same designation is used to mark taxiways that are closed.

Figure 23: Stopway (Overrun) markings

Figure 24: Summary of runway markings

Illuminated Runways

When night flying was introduced, most airports consisted of an open area covered with either turf or cinders. Pilots could land in whatever direction they chose. Rotating beacons provided the pilots with the general location of the airport but did not provide sufficient visual cues to permit them to actually locate the cinder area and land. This problem was solved through the introduction of airport boundary lighting.

Lighting systems on illuminated runways define the outlines of the runway, and are used during times of darkness or low visibility when painted runway markers are not visible. Special purpose lighting systems provide visual glide slope information to the pilot both day and night.

Approach Light Systems

One of the most difficult tasks facing pilots occurs near the end of an instrument approach, during this time they have to maneuver the aircraft into position and land, all within the space of a few seconds. Approach light systems provide the means to transition from instrument flight to visual flight for landing. Operational requirements dictate the sophistication and configuration of the approach light system for a particular runway.

The first approach light systems were quite simple and consisted of three incandescent light bulbs placed 500 feet apart along the extended centerline of the runway. Today approach lighting systems are more elaborate, the specific type of system used is dependent upon the type of aircraft using the airfield. Current systems consist of specially configured signal lights located at the landing threshold and extending into the approach area a distance of 2400-3000 feet for precision instrument runways, and 1400-1500 feet for non-precision instrument runways.

Figure 25: Approach Lighting System as viewed when facing oncoming aircraft.

Figure 26: Diagrams of some standard configurations of approach lighting systems

Figure 8: Concrete runway with markings painted on the surface

Photo Interpretation Training Course

Figure 27: Approach light system near threshold, strobe light in box located in foreground

Some systems include sequenced flashing lights that appear to the pilot as a ball of light traveling towards the runway at high speed (twice a second).

Visual Glideslope Indicators

The angle at which an inbound aircraft approaches the runway is critical to safely landing the aircraft. The ideal point on the runway where the aircraft wheels touch ground is on the touchdown zone located just beyond the threshold. Landing an aircraft at the correct point without assistance from a controller or glide slope lighting system is a difficult task and an unpredictable procedure. If the approach landing angle is too high, there will not be enough runway remaining to accommodate the decelerating aircraft. Conversely, if the approach angle is too low, the aircraft will touch down before the runway threshold and become damaged by intervening obstacles, (trees, lights, fences, etc.). Visual glide slope indicators tell the pilot when the aircraft is on the proper approach angle (not too high and not too low) by a series of light signals that are visible from the air.

There are four types of visual glide slope systems, the Visual Approach Slope Indicator (VASI), the Precision Approach Path Indicator (PAPI), Tri-color systems and the Pulsating system. Of the four types of glide slope lighting systems, the VASI and PAPI are the most common and easiest to identify.

Visual Approach Slope Indicators (VASI)

The VASI is a system of lights arranged to provide visual descent guidance information during the approach to a runway. VASI lights are visible from 3-to-5 miles away during the daylight, and up to 20 miles away at nighttime. The visual glide path that a VASI provides, guarantees safe obstruction clearance to within 10 degrees of the runway centerline and 4NM of the runway threshold. Descent, using the VASI, should not be initiated until the aircraft is visually aligned with

Figure 28: Various configurations of Visual Approach Slope Indicator (VASI) units

the runway. Lateral course guidance is provided by runway markers or runway approach lights.

VASI installations consist of either 2, 4, 6, 12, or 16 lighting units, arranged in bars, (two bar or three bar VASI's). The bars are located on the left side of the runway in the case of 2, 4, or 6 light units, and on both sides of the runway for 12 and 16 light units. The three bar VASI has a near, middle, and far bar, while the two bar VASI system has near and far bars.

The VASI lighting units consist of boxes that project a multi-colored beam of light having a white segment in the upper part of the beam and a red segment in the lower part of the beam. When the aircraft is at too low of an altitude for a given

Figure 29: Visual Approach Slope Indicator (VASI) light units

Figure 30: Quarter view of PAPI light units and windsock. The position of the windsock indicates a lack of surface winds or a "zero" wind condition.

range, only the red beam of light will be visible to the pilot. Landing in this situation would cause the aircraft to touch down before reaching the desired landing zone. If the aircraft is too high for a given distance from the touchdown zone, only the white light will be visible to the pilot. In this instance, the aircraft will land way beyond the landing zone and probably miss or roll off the runway. The lighting units are carefully positioned and their angle is periodically checked so that the pilot using the VASI during an approach will always see the correct combination of red and white lights.

Precision Approach Path Indicators (PAPI)

The PAPI uses multi colored beam of light similar to the VASI. Each lighting unit is installed in a single row of either two or four separate lights. The PAPI system has an effective visual range of 5 nautical miles during daylight and up to 20 nautical miles at night. The single row of lighting units is normally installed on the left side of the runway. Each light faces the aircraft at a different angle, when the aircraft is "on slope" the pilot sees two white lights and two red lights.

Tri-Color Systems

Tri-color visual approach slope indicators normally consist of a single light unit projecting a three color (red-below, amber-above, green-on, slope) visual approach path into the final approach area of the runway. These types of indicators have a useful range of

Figure 31: Diagram showing the relative position of the light on either a tri-color or pulsating light system

approximately one-half to one mile during the day and up to five miles at night depending upon visibility conditions.

Pulsating Systems

Pulsating visual approach slope indicators normally consist of a single light unit (located near the runway end) projecting a two color visual approach path into the final approach area of the runway. A below slope approach is indicated by a pulsating red light, above slope is indicated by a pulsating white light and on slope is shown by a steady white light. The useful range of this system is about four miles during the day and up to ten miles at night.

Alignment of Elements Systems

Alignment of Elements Systems are installed on some small general aviation airports. They are a low-cost system, made of plywood panels, painted black and white or fluorescent orange. Some of these systems are lighted for night use. The useful range for these systems is approximately three quarters of a mile. To use the system the pilot positions his aircraft so the elements appear to be in alignment.

Figure 32: Diagram showing the relative position of the panels in an alignment of elements system

Runway End Identifier Lights (REIL)

Runway End Identifier Lights are installed at many airfields to provide rapid and positive identification of the approach end of a particular runway. The system consists of a pair of synchronized flashing lights located laterally on each side of the runway threshold. REILs may be omnidirectional or unidirectional facing the approach area.

REILs are used for:

1. Identification of a runway surrounded by a preponderance of other lighting.
2. Identification of a runway that lacks contrast with the surrounding terrain.
3. Identification of a runway during periods of reduced visibility.

Figure 33: Diagram showing placement of Runway End Indicator Lights (REIL) and threshold lights

Figure 11: Runway overrun and barrier net

An **arresting gear** is a type of barrier system device consisting of an elevated cable connected to reels mounted on both sides of the runway. It is used for the purpose of stopping tail hook and non-tailhook equipped aircraft. A cable is stretched across the runway and is caught by the tail hook or landing gear of the inbound aircraft, as the cable is stretched the energy of the aircraft is reduced thus preventing the aircraft from going beyond the overrun. Arresting gear cable systems are usually located just beyond the designated wheel touchdown zone.

Chapter 3

Cultural Features

Figure 34: Runway End Identifier Light (REIL) system approach end of an asphalt runway

Figure 35: A runway edge light and a taxiway light

Runway Edge Light Systems

Runway edge lights are used to outline the edges of runways during periods of darkness or restricted visibility. Runway edge lights are white, except on instrument runways where amber lights indicate the last 2000 feet of the runway or the last half of the runway thus forming a caution zone for landings. Taxiway edges are marked by blue edge light fixtures.

Threshold Lights

Threshold lights marking the runway ends emit a two colored directional beam which is used to distinguish the runway threshold from the runway end. The red portion of the beam faces inward, indicating the runway end to a departing aircraft, a green light facing outward from the runway indicates the threshold end for inbound aircraft. Runway edge lights and threshold lights are usually 12 to 18 inches tall.

Figure 36: Threshold Lights

Runway edge lights are white, except on instrument runways where amber lights indicate the last 2000 feet of the runway or the last half of the runway thus forming a caution zone for landings. Taxiway edges are marked by blue edge light fixtures.

Threshold Lights

Threshold lights marking the runway ends emit a two colored directional beam which is used to distinguish the runway threshold from the runway end. The red portion of the beam faces inward, indicating the runway end to a departing aircraft, a green light facing outward from the runway indicates the threshold end for inbound aircraft. Runway edge lights and threshold lights are usually 12 to 18 inches tall.

Figure 36: Threshold Lights

In-Runway Lighting

Touchdown zone and centerline lights are installed on some precision approach runways to facilitate landing in adverse visibility conditions. Taxiway turnoff lights may be added to expedite movement of aircraft from the runway. The lights are flush mounted at or below the runway surface and are seldom detectable unless viewed from above in low light conditions.

Threshold Lights Touchdown Zone Lighting (TDZL) consists of two rows of transverse light bars disposed symmetrically about the runway centerline in the runway touchdown zone. The system starts 100 feet beyond the landing threshold and extends to 3000 feet from the threshold or to the midpoint of the runway, whichever is the lesser.

Runway Centerline Lighting Systems (RCLS) consist of flush mounted centerline lights spaced at 50 foot intervals beginning 75 feet from the landing threshold and extending to within 75 feet of the opposite end of the runway.

Figure 37: Touchdown zone lights and runway edge lights

Taxiways

Although there are different types of taxiways, the main purpose of a taxiway is to provide a dedicated surface for the orderly movement of aircraft to and from the runway. Taxiways are paved with as many types of surface materials as are runways, however taxiways are not always paved with the same material as the runway they serve. The width of the taxiway is considerably more narrow than the runway (usually just wide enough to allow the landing gear to roll on pavement), and the overall thickness of the pavement is thinner than the runway. Taxiways are marked differently than runways, but in some instances they are mistaken for the runway itself. There are five primary taxiway types: parallel, loop, perimeter, dispersal, and link.

Figure 38: Runway centerline lights

Parallel Taxiways

As the name implies, the parallel taxiway is oriented along the same axis as the runway. This taxiway permits aircraft roll to the appropriate end of the runway (for take off or exiting runway), without obstructing the runway.

Parallel taxiways are sometimes mistakenly identified as parallel runways because of their similar orientation. To reduce the frequency of this common mistake, the analyst should remember that taxiways are more narrow than runways, and they lack approach markings and approach lights. Parallel taxiways are connected to the runway by link taxiways located at both runway ends, and at selected points along the length of the runway.

Figure 39: Diagram of a small airfield showing the relationship of the various types of taxiways

Link Taxiways

Link taxiways, (also called connecting links) are used to connect runways, parking facilities and other taxiways. Link taxiways have the same marking, lighting, measurement and pavement types as do all other taxiways.

Loop Taxiway

Loop taxiways are located at one or both ends of the runway, and look just as the name describes. The turning loop allows aircraft to taxi to the runway end, and turn around into the wind before take off. When landing, aircraft roll to the runway end, enter the loop taxiway, then follow the taxiway across the runway or to a parking area.

Figure 40: Diagram of a larger military airfield showing the relation between the taxiways, runways and other facilities.

Perimeter Taxiway

The perimeter taxiway connects the runway with maintenance, cargo, munitions, parking, and passenger areas on non-consolidated airfields that have service facilities spread over a large area. Because this taxiway is not located in the immediate vicinity of the runway and does not always follow a straight line, it is sometimes mistaken for a service road. Perimeter taxiways are wider than service roads and do not connect with main thoroughfares.

Dispersal Taxiways

The dispersal taxiway is only found on military airfields, it provides quick access to the end of the runway for departing aircraft and connects the runway to dispersal parking areas where alert aircraft are normally parked. Dispersal taxiways can be straight or curved, with numerous links connecting dispersal parking areas with the taxiway. Dispersal areas are located at one or both runway ends.

Taxiway Markings

Taxiway centerlines are marked with a painted, continuous yellow line. Taxiway edges are marked with a continuous double line that is separated by six inches.

Holding Lines

Holding lines are found on taxiways, and are used to indicate where aircraft should stop and wait before entering an active runway. They serve a similar purpose as the white lines found at automotive traffic light crossings. Holding lines are placed a sufficient distance from the runway edge to prevent inbound landing aircraft from making physical contact with waiting outbound aircraft.

Figure 41: Taxiway markings

Taxiway Lighting

Taxiway edge lights are used to outline the edges of taxiways and are illuminated during periods of darkness or restricted visibility conditions. These fixtures emit blue light.

Taxiway centerline lights are used to facilitate ground traffic under low visibility conditions. The flush mounted lights are steady burning lights that emit a diffused green light.

Figure 42: Elevated Taxiway lights

Aircraft Parking Areas

Aircraft parking areas are connected to the runway by taxiways. There are two types of aircraft parking areas, the apron and the hardstand. Each type provides a stable area for aircraft to park while involved in a variety of non-flying functions such as fueling, cargo/passenger services, maintenance, etc. The function or specific activity performed at a parking area is described in its name. The parking area name describes the appearance or functional design of the aircraft parking site.

Apron Parking Areas

Apron parking areas are associated with both military and civilian airfields. They are rectangular or square shaped areas, and are paved with a wide variety of surface materials. The paving material selected will vary depending upon the climate, the amount of traffic, the wheel load weight of the aircraft using the airfield, the size of the parking area and the specific type of surface material. Apron parking areas are subdivided into nine different types, named for the design or function performed at each apron. They are: general field parking, alert, operational, hangar, base flight, pad, transient, depot and stub aprons.

General Field Parking

This type of facility consists of a natural surface area (usually sod) for parking aircraft safely away from the operational areas at the airfield. Field parking areas are not easily identified; at their worst they closely resemble grass areas found on the surrounding airfield. Fortunately there are a few subtle signatures at some field parking areas that will aid in their identification.

Designated parking spaces, visual tie down points and grounding rods are sometimes present at field parking areas. The spaces are defined by the average wing tip to wing tip length of the aircraft that use the airfield. Each space is separated

Figure 43: General field parking (grass surface) with aircraft tie downs

by enough distance to prevent damage to other aircraft when an aircraft is moved in or out of a parking space. At field parking, aircraft parking spaces are sometimes outlined with used aircraft tires that have been painted white. The tires are placed on the ground at regular intervals to define the appropriate tie down points.

At air shows or large deployments of a temporary nature, the perimeter and entrances of field parking areas are often defined as rectangular areas and are delineated by surveyors tape or lime powdered lines. Parking spaces in these areas are not defined, each aircraft is parked next to the other.

A method of identifying general field parking areas is by comparing the height of the grass at the airfield. On parking areas and runways the grass is mowed closer to the surface than the grass that covers the non-operational open areas of the airfield. The mowing pattern and smooth texture of the shorter cut grass forms a smooth textured, clean rectangular shape when contrasted against the rough, unmowed background.

Figure 44: General field parking with aircraft tied down

Identification of taxiways that connect field parking areas with the airstrip can sometimes be made by detecting aircraft tire tracks that have been worn into the turf or surface material. Repeated aircraft crossings and wet conditions increase the tire tracks in the taxiway and field parking area.

In the absence of the above mentioned indicators, field parking areas cannot be distinguished from open grass areas.

Alert Aprons

Alert Aprons exist to provide a separate parking area for military combat aircraft. Alert aircraft are continuously kept loaded and ready for combat with aircrews on twenty four hour standby, to fly the aircraft in the event of war. The general appearance of the alert apron is vastly different from other parking aprons.

Alert aprons are located near the runway ends and are surrounded by a cleared area with security fencing. They are usually occupied with combat aircraft parked in a well dispersed, sequential manner and are served by a single taxiway. The presence of an alert bunker or ready room for the aircrews is a characteristic of the alert apron.

Fully loaded alert aircraft remain parked for long periods of time in the same location on the alert apron, thus resulting in continuous stress on the apron pavement. This type of wear and tear can only be sustained by the application of a paving material that remains stable under load, during wet weather or high temperatures. The two most commonly used paving materials for alert aprons are cement and pierced steel planking.

Apron floodlights are used to illuminate alert aprons and their security fence lined perimeter.

Operational Apron

The operational apron is the most commonly found apron type. Its only distinct identifying characteristic is the presence of rows of parked aircraft. The operational apron is used to temporarily park aircraft that are not engaged in any activity. Operational aprons are paved with all types of paving materials, or may have non-paved natural surfaces. They are well illuminated by apron floodlighting and are usually served by more than one taxiway.

Figure 45: An operational apron at a major military airfield

Hangar Apron

The parking area located immediately before a hangar door opening is the hangar apron. This type of apron serves as a temporary parking area to store aircraft that have completed or are awaiting servicing/storage in the hangar. The hangar apron is usually illuminated by hangar floodlights. Entry stripes are marked on the apron to enable the aircraft pilot to safely enter or exit the hangar with adequate clearance.

Figure 25: Approach Lighting System as viewed when facing oncoming aircraft.

Chapter 3

134 Cultural Features

Figure 46: Hangar apron in front of two single bay hangars

Figure 47: Base flight apron

Base Flight Apron

The base flight apron is the apron with the most activity at the airfield. Incoming and departing flights stop there to transfer passengers and cargo. Aircraft on this apron will usually occupy the area for a very brief time. Multiple taxiways serve this apron and apron floodlighting is always present. The paving surfaces for this apron are usually made of cement or pierced steel planking, however exceptions to this are found at less improved airfields.

Transient Apron

Transient aprons are similar in appearance to other parking aprons. Located away from the main activity area of the airfield, they are occupied by aircraft that are not permanently home-stationed at the airfield. Aircraft refueling is usually accomplished by trucks on this apron and security services are provided when necessary. At military airfields, the transient apron may contain aircraft types that are noticeably different from the majority of the aircraft normally found there. This is the best signature for determining the presence of a transient apron.

Photo Interpretation Training Course

Figure 4B: Military aircraft refueling at a transient apron

Pad Apron

A pad apron is a simple apron that is not associated with any structures. It is alone and not connected to the runway by a taxiway. The pad apron can be used for a wide variety of activities and is only identified by the absence of any adjacent structures. The surface materials used to pave a pad apron cover the whole range. Apron lighting on pad aprons is not essential.

Depot Aprons

Depot aprons are co-located with cargo handling facilities. The presence of specialized off-loading equipment, warehouses, and delivery trucks are the primary features that differentiate the depot apron from other parking aprons. Because most cargo flights arrive and depart at nighttime, the presence of apron flood-lighting to assist the transshipment of cargo is a necessity. Compared to passenger terminals, depots have noticeably less civilian vehicle parking.

Stub Apron

The stub apron is a parking apron that is directly attached to the runway without the benefit of a taxiway. Stub aprons can be found along the edge of the runway or on either end of the runway just beyond the threshold. Stub aprons are used for a variety of purposes, and they provide a safe place to exit the runway when another plane is coming in for a landing.

Hardstand Aircraft Parking

Hardstands are improved parking areas that are found predominantly on military airfields. The presence of a parking hardstand at a civilian facility is very rare.

Hardstands are built to provide parking areas for military aircraft. Each hard-stand is separated from the other by an interval that is large enough to prevent an explosion in one from damaging aircraft parked in adjacent hardstands.

Hardstands are used for many specific types of aircraft activities and purposes.

There are ten types of hardstands to accommodate the various uses: alert, dispersal, pad, refueling, parking, operational, engine run-up, firing-in, compass rose and maintenance hardstands.

Finding an observable difference between the many hardstand types is sometimes difficult. The location, cleanliness, security, and quantity of hardstands provide clues to their specific use, thus giving the analyst enough information to classify them by type. Hardstand parking areas look much different from parking aprons. In general, the hardstand can best be described as a round or square asphalt or cement pad, connected to a runway or taxiway. From above they appear to have the same shape as an antique keyhole or a cul-de-sac street.

Hardstands can be built to accommodate all types of aircraft from large to small depending upon the size that is required. Although they are normally occupied by one aircraft, some have enough space to park two aircraft side by side. The materials commonly used to pave the hardstand parking pad are concrete, pierced steel planking (PSP), membrane, and occasionally asphalt over concrete.

Dispersal Hardstands

Dispersal hardstands provide separate parking spaces for military aircraft. They are separated by a distance great enough to prevent neighboring aircraft from sustaining damage due to fire and explosion in another. Dispersal hardstand parking areas were designed as a response to the lessons learned from the damage that was inflicted upon aircraft parked wing tip-to-wing tip at Hickham Airfield, (Pearl Harbor, Hawaii) in 1941.

Dispersal hardstands are located away from the runway, and are connected to the runway by loop taxiways. Loop taxiways permit aircraft to enter and exit the dispersal area without having to back up and turn around at a dead end. Entry/exit taxiways for dispersal hardstand parking areas are located off the runway ends, and at various points along the length of the runway.

Alert Hardstands

With only a few exceptions, alert hardstands have the same general appearance as dispersal hardstand parking areas. These facilities are purposely located at the ends of the runway to provide quick access to the take-off end of the runway for departing aircraft.

Because they contain numerous aircraft that are combat ready (loaded with conventional or nuclear ordnance), security measures at alert facilities are more restrictive than at dispersal hardstand areas. Multiple rows of security fences, lighting, guard towers and control points regulating the passage of aircraft and vehicles are all characteristics of the alert facility. Shelter for the ever-present alert aircrews and ground support personnel, is provided by an alert building or bunker.

Figure 29: Visual Approach Slope Indicator (VASI) light units

Photo Interpretation Training Course

Transportation

Cultural Features 137

Taxiways serving the alert facility are predominantly of the loop type, and are not excessively long, thus minimizing the distance from hardstand to runway end.

The presence of aircraft at an alert facility is not a necessity for accurate identification of an alert hardstand area to be made. During an aircraft alert exercise it is common for all alert aircraft to depart the facility. Most of the time an operational alert facility is occupied by many aircraft, thus there will be many hardstands.

Operational Hardstands and Parking Hardstands

Operational hardstands and parking hardstands both serve as places to park aircraft and have nearly identical appearances. The only difference between them is distinguished by their location relative to other structures at the airfield. Usually only one or two of these hardstands exist at an airfield.

Operational hardstands

Operational hardstands provide temporary parking for single aircraft that regularly arrive at the airfield. They are usually located near hangars and cargo/passenger terminals.

Unlike dispersal hardstands, these hardstands are either connected to the runway by link taxiways, or are branches off other taxiways or parking aprons.

Parking hardstands

Parking hardstands are located away from other aprons, hangars, and similar high use areas at the airfield. Small groups of parking hardstands are used for temporarily parking single resident and non-resident aircraft.

Figure 49: Parking hardstand on edge of apron (poorly maintained)

Photo Interpretation Training Course

Figure 50: Diagram of a military airfield showing the location of dispersal hardstands.

Figure 51: Diagram of a military airfield showing the location of various types of hardstands.

Engine Run-up Hardstands

Engine run-up hardstands have several characteristics that make them identifiable. Jet propelled and turbo-prop aircraft engines require occasional preflight stress testing at very high RPM ranges. The amount of exhaust and noise generated is significant enough to be a health and hearing hazard. One of the facilities that was designed to accommodate this activity is the engine run-up hardstand. Hardstands are located and oriented away from populated areas. They are equipped with blast deflectors that direct the resulting exhaust blast and noise up and away from the surrounding area. The engine run-up hardstand is usually located near a parking apron or next to the runway.

Figure 52: An engine run-up hardstand with blast deflectors

Firing-In Hardstands

Firing-In Hardstands are constructed at military airfields only. The sole function of a firing-in hardstand is to provide a parking pad for combat fighter aircraft while having their machine guns or nose cannon zeroed-in and aligned.

The firing-in site is essentially an aircraft parking area at the end of a firing range. When viewed from above, the site is rectangular in shape and consists of a circular parking pad set opposite from a tall and wide earthen-walled target area. Along each side of the range connecting the pad and target area, are two long, tall earthen walls that are separated by a distance equal to the wingspan of the aircraft using the facility.

The arrival of laser gun sighting systems and optical sight devices has all but eliminated the necessity to fire live ammunition at these facilities. Although new sighting-in technology has enabled incredible accuracies to be acquired, the need to sight in on targets while remaining shielded from outside disturbances is a prerequisite that the old sites still satisfy. Thus the need for firing-in hardstands continues.

There is only one firing-in hardstand per airfield, and they are only found at airfields built to support specific types of fighter aircraft.

Compass Rose Hardstands

This type of hardstand is associated with both military and civil airfields, it is one of the easiest hardstands to identify. The compass rose hardstand is used as a reference to calibrate the various compasses on board an aircraft. A compass rose that is subdivided into sections, is laid out and painted on the surface of the parking apron. Aircraft are taken to a reference point on the apron where the actual aircraft compass heading is compared to the figure inscribed on the

Figure 36: *Threshold Lights*

Photo Interpretation Training Course

Chapter 3

140 Cultural Features

Figure 53: *A compass rose hardstand*

painted compass rose. The process of compass calibration is performed at all four cardinal directions. If minor differences between the aircraft compass reading and the ground truth figures are discovered the variation is noted and allowed, for more serious variations, the compass is replaced or repaired.

Compass rose hardstands are not associated with a specific area or location on the airfield. The only identifying characteristic of this hardstand is the presence of a compass rose painted on the hardstand surface.

Maintenance Hardstands

Various types of aircraft maintenance tasks are performed at the maintenance hardstand. Minor repair work such as fixing hydraulic fluid leaks, avionics box replacement, lubrication, tire replacement, and engine replacement are routinely performed outdoors on the maintenance hardstand. These hardstands are found at military and civilian airfields. At military airfields the maintenance hardstand is generally located within a dispersal hardstand area. When present at civilian facilities, a maintenance hardstand is generally located near an operational apron. The maintenance hardstand is characterized by the presence of special purpose vehicles, van-bodied trucks, noise abating equipment, oil stained pavement, environmental shelters and portable lighting units.

Refueling Hardstands

The refueling hardstand serves the purpose for which it was named. The primary characteristics that denote this feature are: stained pavement from fuel spills, the presence of fuel pumps or fuel vehicles, and lighting fixtures. At military and civilian airfields, refueling hardstands can be found within dispersal areas, alone near operational aprons, or near the base fuel storage facility.

Photo Interpretation Training Course

Revetted Hardstands

Although all hardstands that provide parking for military aircraft are subject to attack during wartime, the revetted hardstand is a somewhat hardened defensive structure. In order to protect parked aircraft from lateral blast damage, an earthen wall (revetment) is placed around the hardstand parking pad. The revetment surrounding a hardstand parking pad is tall enough to protect all parts of the aircraft from flying debris and shrapnel.

Revetted hardstands are usually found at dispersal and alert hardstand parking areas. To control erosion and aid in concealment, grass is planted on the revetment. When planted, mowed and cared for, revetments blend into the terrain. As a defensive structure, revetments work quite well, their height and varying orientation make them very difficult targets for low altitude attacking aircraft.

A common form of concealment employed at revetted hardstands involves stretching camouflage netting over the top of the revetment. This technique inhibits the ability of low-flying attack aircraft to detect and destroy parked aircraft on the hardstand pad. A common mistake made by analysts is to misidentify the net-covered, revetted hardstand for an aircraft bunker.

Figure 54: *Revetted hardstand*

Aircraft Bunkers and Hardened Aircraft Shelters

The aircraft bunkers and hardened aircraft shelters are defined as man made, reinforced structures that normally provide environmental shelter for one or more aircraft and provide a degree of protection from attack. These structures are only associated with military aircraft, and are found in dispersal areas and alert facilities. From above, three structural components are visible to the analyst, they are: blast doors, exhaust vents, and the shelter or bunker itself. At some sites multiple sets of blast doors are installed. The outermost set of doors act as a shield to absorb the explosive force of an incoming weapon, thus protecting the actual bunker doors from blast damage and penetration.

Aircraft Bunkers

Aircraft bunker construction begins by erecting a quonset or arch shaped structure (made of prefabricated arch shaped cement and steel segments), over a hardstand parking pad. After assembly of the inner structure and the addition of exhaust vents is completed, blast doors (sliding, hinged, or clamshell type) are installed on the opening of the structure. At this stage of construction the shelter can be considered complete. For airfields with requirements that demand a more

Figure 55: Aircraft bunker

hardened structure, the sides, back and top of the arch-shaped inner structure are covered with a 10 to 15 foot layer of earth. When left uncovered, the structure is referred to as a **hardened aircraft shelter**, when earth covered it becomes an **aircraft bunker**. Aircraft bunkers and hardened aircraft shelters both provide a highly blast resistant shelter for aircraft, and prohibit reconnaissance flights from detecting the number of aircraft present at the facility.

The taxiways leading to the aircraft shelter or bunker, and the blast doors are frequently camouflage painted, as is the surface of the hardened aircraft shelter. Some bunkers have bushes and other types of vegetation intentionally planted on them to make them more difficult to detect.

Occasionally, the blast doors on aircraft shelters are left in the open position to permit aircraft to enter and exit the structure. The ability to see the blast doors or look into the structure is dependent upon the orientation of the bunker entrance and the position of the observer. Dispersal areas and alert facilities are designed so that the entrance of each aircraft shelter/bunker faces a different direction thus making it impossible for an attacking aircraft to have a direct shot at more than one or two shelters per pass.

Figure 56: Side view of an aircraft bunker

Aircraft Shelters

An aircraft shelter is defined as a man-made structure with two or fewer walls, designed to provide overhead protection and concealment for one or two aircraft. Aircraft that are parked in these shelters are protected from small particles of falling debris and they are shielded from the environmental effects of rain, hail, snow, and sunlight. At military installations, concealment from overhead reconnaissance platforms is an on-going threat that is neutralized by parking beneath an aircraft shelter. An aircraft shelter is the airfield equivalent of the automotive carport.

Always built on top of hardstands or aprons, aircraft shelters are usually light-weight metal frame structures, covered by gable or flat, corrugated metal roofs. Other variations consist of arch or semi-hexagonal shaped structures made from prefabricated components.

An extra measure of blast protection can be obtained by adding an earthen, sandbag, or cement revetment around the outer edge of the open sided shelter.

Figure 57: Aircraft shelter (cantilevered roofs)

Aircraft Tunnels and Underground Complexes

Tunnels and underground complexes are the most difficult of all hardened facilities to detect. These facilities are buried completely below the ground, and even the ventilation shafts are sometimes camouflaged. The only way to find this type of structure is to locate the entrance by following all the taxiways and roads that leave the airfield and determine whether they lead to a tunnel opening. Because access to the runway is critical for flight take off, a pathway leading to the tunnel or underground entrance will always be present. The entrances are sometimes made more difficult to find by placement of natural vegetation, intentional concealment by shadowing, camouflage netting, or disruptive painting.

Construction materials used at these sites are reinforced concrete, metal arches, or layers of concrete. Steel blast doors may be built to protect the tunnel openings. When underground facilities are under construction, numerous dump trucks carrying rock and earth tailings can be observed going in and out of the construction site and area.

Underground structures are utilized extensively in Norway, North Korea, Taiwan, China, Switzerland, and Sweden.

Figure 42: *Elevated Taxiway lights*

Photo Interpretation Training Course

Hangars

The aircraft hangar is one of the first structures specifically designed for, and only associated with aviation. Early aircraft hangars were adaptations of existing structures (barns and agricultural buildings) that occupied the farm land where airstrips were first built. At ranches and farms with grass landing strips, modified barns and farm buildings still serve as hangars.

Hangars are associated with all types of fixed wing aircraft and helicopters, and are generally the largest and easiest to identify structures found at the airfield. Some of the largest hangars ever constructed were designed for lighter-than-air aircraft, blimps and airships.

Of the many aeronautical functions performed in hangars, the most common activities are heavy and light maintenance, aircraft storage, airframe assembly and construction, aircraft concealment, and airframe painting. Workshops, machine shops and parts storage/distribution offices occupy space within some aircraft hangars and usually take the form of shed type structures or appendages connected to the side of the main hangar structure.

Design Variations

Some aircraft hangar architects created designs that radically departed from the usual aircraft hangar. In recent years, folding quonset-shaped aircraft hangars for small aircraft have appeared. They are covered with waterproof, opaque fabric and have an appearance similar to inflatable gymnasium structures. The outer covering is made of waterproof fabric that is suspended by a rigid inner framework. Entrance into the hangar is accomplished by raising or lowering a semi-spherical, hinged flap type door located on either end of the structure.

Other unusual hangar types that may be seen are cylindrical hangars that resemble POL storage tanks. Access to the hangar is accomplished through a set of curved hangar doors mounted on tracks that curve around the side of the hangar.

Construction Material

The most commonly used building materials associated with hangar construction are concrete, masonry, wood, and steel. For strengthening the framework and covering the walls and doors, metal sheeting and masonry are most often selected. Asphalt shingles, metal sheeting, and tar and gravel roofing are the most common materials used for aircraft hangar applications. Hangars usually have arch or gable roofs. Occasionally shallow pitch or flat roofs are chosen for smaller hangars or in areas with little rain or snow.

Figure 4.3: General field parking (grass surface) with aircraft tie downs

Photo Interpretation Training Course

Transportation

Cultural Features 145

Signatures

The signatures that differentiate aircraft hangars from other structures at an airfield are: large sliding doors, hangar parking aprons, close proximity to the runway, and the presence of aircraft parked nearby. Hangars always have an attached hangar apron with a taxiway connecting to the runway. Hangars are usually the largest structures at an airfield.

Doors

The doors that are used in over 90% of all hangars are of the sliding door type. Sliding doors are mounted on an overhead rail or track that permits the door to slide open parallel to the face of the hangar. To create an opening as wide as the interior of the hangar, the doors must travel a distance equal to the opening. To accomplish this, overhead door rails that extend beyond the front sides of the hangar opening are added to the structure.

Hangar Door extensions are clearly visible when the door is in either position. With the door open, the hangar will appear to have one or two solid ears extending from the face of the hangar. In the closed position the overhead rail and vertical support members are visible and will cast prominent shadows across the ground.

A variation of the external sliding door is the internal sliding door. This door type differs mainly because the overhead rail and extensions are mounted on the interior of the hangar and each door is divided into segments. This type of hangar door assembly allows the door segments to stack upon themselves and occupy a smaller amount of storage space.

A type of door mechanism used on medium to small hangars is the horizontal bi-folding door. This type of door is made from a solid panel that is divided horizontally into two sections of equal size. The counterweighted and hinged upper and lower door sections are mounted on vertical tracks that allow the doors to fold outward and upward. They join and form a single section that is stored in the ceiling above the intended aircraft parking space, on the mounting track. For ventilation and lighting purposes this type of door is sometimes observed in the partially open position, not completely stored in the hangar ceiling. When the door is left in the partially open position and viewed from above, the hangar will appear to have a flat awning extending over the doorway opening.

Hangar Types

As time passed and aircraft designs changed, a wide variety of architectural solutions for aircraft hangar design also emerged. A simple system of hangar design classification was devised to name specific hangar types. Seven types of hangars were identified and named on the basis of their shape, capacity, and location (above or below ground), they are: multi-bay, open end, nose, underground, single bay, double bay, and T-shaped.

Photo Interpretation Training Course

Figure 58: Multi-bay hangars

Multi-Bay Hangars

Multi-Bay Hangars are aircraft hangars that have three or more hangar door openings along the same face of the building, and are covered by a common or separate roof. Hangars with only two aircraft bays are not classified as multi-bay hangars. Each door opening delineates a separate open area or bay that accommodates a single aircraft. When a series of three or more hangars are joined and share common load bearing side walls, they are labeled as “multi-bay” hangars.

Single row multi-bay hangars usually have flat or shed type roofs and are covered with painted steel panels supported by a steel or wood interior framework. Each aircraft bay is joined to the next by an interior load bearing wall that is not visible from outside or above the building. Multi-bay hangars share a common roof, and outer wall covering. This hangar type is characterized by long and narrow proportions, whereas single bay hangars are nearly square in shape.

Multi-bay hangars can also be configured as double row structures. The double row configuration looks similar to the single row multi-bay hangar, however it is a structure formed by two rows of separate hangar bays that are joined side-by-side by load bearing walls, and connected back-to-back. The result is a hangar that opens outward along both long sides, onto two hangar aprons. The double row configuration is usually covered by a shared, low pitched, gable roof that is peaked along the long axis of the structure.

Overall, both configurations of the multi-bay hangar can give the impression of being a large warehouse type of structure, however the presence of one or two hangar aprons, separate hangar bay door openings, and nearby parked or taxiing aircraft reveal it's true identity.

Single Bay Hangars

The single bay hangar represents the most commonly used design for aircraft hangar construction. This hangar type is characterized by having a single door opening on one or both ends of the structure and hangar aprons on either side. The single bay hangar typically has a curved, gable, or flat roof.

Early structural engineers were asked to design a hangar with an open interior floor space, free of vertical support obstructions such as poles and uprights, the resulting effort yielded a hangar with unobstructed floorspace that permitted easy movement and parking of numerous aircraft. The structural engineering methods and solutions used to create these hangars utilized external devices such as buttresses and vertical support columns that are sometimes visible along the outer hangar walls.

The proportions of the average single bay hangar range from equal on both sides to being somewhat longer than wide. Each hangar is sized to fit the aircraft that will be using it, the proportions of wingspan width to fuselage length are close to equal for most non-combat aircraft. The height of single bay hangars varies from one to three stories tall, the only exceptions are blimp hangars that are sometimes as tall as six stories.

Figure 59: Large single bay hangar with internal sliding doors and arch roof

Double Bay Hangars

The double bay hangar is similar in appearance to the single row multi-bay hangar. Characteristics of the double bay hangar are the presence of two separate aircraft bays, and two separate hangar doors. Construction materials and roof types are the same as used on single bay hangars.

Nose Hangar

The nose hangar is a specially designed structure that provides sheltered parking for the nose portion, fuselage and wings of large aircraft. Most of the nose hangars in existence are modifications of single-bay hangars. When modern cargo and passenger aircraft were introduced to commercial use, their increased length and tail section height exceeded the interior capacity of most existing hangars. An economical solution to this dilemma was to park the nose, fuselage, and wing sections of the aircraft inside the hangar, and modify the hangar door such that when closed it would encircle the fuselage of the aircraft, leaving the tail section exposed to the elements. Fortunately, the portions of modern aircraft that are

Figure 60: Nose hangar

able to fit inside of existing hangars are also the parts of the aircraft that frequently require maintenance.

Positive identification of a nose hangar can be made only under two conditions:

1. When the tail section is visibly jutting out of the hangar,
2. when the hangar is unoccupied, with doors closed, and hangar door cut-out modifications are visible.

T-Shaped Hangar

T-shaped hangars can accommodate one aircraft per hangar, and are usually used to shelter small aircraft. The T shape design conforms to the proportions of the airplane. The narrow leg of the "T" accommodates the tail and fuselage, while the

Figure 61: Hangar configurations

upper bar part of the "T" houses the wings and engines. The front of the T-shaped hangar, (the widest side) is where the hangar door is located, thus aircraft entering the hangar must be pushed in tail first. These structures are usually made out of steel sheeting over wooden pole interior frames. The door types associated with this structure are bi-fold, sliding, or outward opening hinge type doors.

The T-shaped hangar is usually a stand alone structure. Occasionally one or more T-shaped hangars are joined resulting in a structure that does not exhibit the characteristic "T-shaped" signature.

Open End Hangar

The open end hangar is characterized by low, long, narrow, rectangular, slanted-roof structures, that are open along one side and have no less than three walls. The open side, or hangar entrance extends along the entire length of the long side of the structure. Entrance to the hangar is made by backing aircraft in through the open side. These hangars are usually associated with small aircraft and provide environmental protection for one to fifteen aircraft.

Open end hangars are usually covered by sheets of steel or wood siding, and have metal roofs that are supported by a wooden pole internal framework. Like all hangars, the open end style is located near the flight line, and will have a parking apron in front of the hangar door opening.

Maintenance Shops and Facilities

Most airfields have facilities where maintenance activities are performed. The number and types of aircraft served at an airfield generally provide an indication of the level of maintenance activity performed there.

Small airfield maintenance facilities

Small airfield maintenance facilities that serve private, non-commercial and non-military aircraft generally have shops that perform routine maintenance activities. Small airfield maintenance shops require only a small amount of space and few,

if any specialized work or storage areas. The activities performed in a small maintenance facility are similar to those performed in neighborhood automotive repair shops. Correspondingly, there are few employees and the amount of floor space occupied is small. Workshop rooms and tool storage closets

Figure 62: Single bay hangar with added maintenance workshop

are usually incorporated into the interior design of the hangar. Some are connected to the sides of the structure as appendages, wing additions, or sheds.

Medium and large airfield maintenance facilities

Medium and large airfield maintenance facilities that serve commercial or military aircraft have special buildings and storage areas where maintenance activity is performed. The difference between aircraft maintenance activities at medium and large facilities and that which occurs at smaller airfields, lies mainly in the amount of aircraft served and in the greater technical sophistication of the duties performed there. Maintenance of a higher order, such as engine swapping, minor airframe repair, painting, parts inventory and warehousing are a few of the activities that take place at these facilities.

The need to serve greater quantities of customers and larger types of aircraft, creates the requirement to have bigger repair shops with more room to store replacement parts. Military regulations require a certain amount of engine spares and replacement parts to be on hand at all times, (a concept shared by many civil aviation organizations) thus the need for parts warehouses. At most facilities

there is an outdoor storage area for engine containers and crates containing large spare parts. Many specialized vehicles, such as lift equipment, handling vehicles, work platforms, "cherry pickers" etc., are commonly found parked throughout the maintenance facility. Air compressor buildings and high pressure welding gas storage bins are important "small dimension" features found at these facilities.

The presence of aircraft parked on oil stained maintenance aprons, left in various stages of disassembly and/or surrounded by environmental canvas shelters also denotes the aircraft maintenance area. Some hangars are designated as "maintenance hangars" and the maintenance activity is sometimes observed on the apron in front of the hangar.

Figure 63: Airfield diagram showing relative location of maintenance facilities

Figure 49: Parking hardstand on edge of apron (poorly maintained)

Photo Interpretation Training Course

Transportation

Cultural Features 151

Jet Engine Test Cells

Jet engine test cells and maintenance hardstands with blast barriers are usually present in maintenance areas where engine run-up tests are performed. There are several design variations of the engine test cell. Significant features that they share in common are:

1. a covered stand where the aircraft engine is mounted (or the aircraft is parked), and
2. an exhaust tunnel or duct that is connected to a deflector building. The roof of the deflector building is covered with openings that direct the resulting noise and exhaust blast upward and away from the immediate and nearby populated areas.

Another type of engine test cell is the "hush house," it allows the engine to be tested while it is still mounted inside of the aircraft. The hush house serves the same purpose as a test cell, but has a larger building at the cell front. It is served by a taxiway instead of an access road.

Figure 64: Engine test cell

Figure 65: Jet Engine Test Cell

Photo Interpretation Training Course

Cargo and Passenger Handling Facilities

Cargo and passenger handling facilities and their related pieces of equipment constitute important parts of military and civilian airfields. Virtually every airfield, regardless of its size, receives passengers and cargo. At some airfields cargo and passenger facilities sometimes share a common building. Airfields that handle a high volume of cargo deliveries usually have a separate cargo handling area that is located away from the passenger terminal. In either case, it is relatively easy to distinguish the shared from the separated facilities.

Cargo and Air Freight Facilities

The unique characteristics that define cargo and air freight facilities are their location at the airfield, and the cargo handling and transportation vehicles that are associated with them. The cargo shipping and receiving building is a long, narrow single-story structure with a parking apron that is connected to the main runway by a taxiway. One of the long sides of the structure faces the aircraft parking apron and the other is bordered by a loading dock facing the cargo truck parking lot. The facility is road served with access to main highways. The overall appearance of the structure resembles a warehouse. The cargo that is handled in an airfield cargo facility is being transshipped and is only stored there for a short period of time.

Figure 66: Cargo handling facility

On the airstrip side of the cargo handling facility, the parking apron is illuminated by apron floodlights, and is occupied by various handling vehicles such as forklifts, tow motors and trailers. Aircraft being loaded/unloaded are not always present on the cargo parking apron when it is observed. When not actively engaged in loading cargo aircraft, the transfer vehicles and handling equipment are usually parked on the apron's edge or inside of the warehouse structure.

Figure 67: Diagram of a major civil airfield, showing passenger and freight terminals.

Passenger Facilities

Passenger facilities are characterized by passenger ramps leading to the aircraft, passenger handling vehicles, baggage handling trolleys, long and short term parking garages/lots, and the airport terminal building. Although activities such as cargo handling and passenger transfer take place at all airfields (regardless of their size), not every airfield has recognizable passenger facilities and equipment.

Passenger facilities at large and medium airfields have passenger ramps or "air stairs" that enable people to easily walk into the aircraft without having to climb ladders or negotiate other inconvenient devices. Baggage loading and unloading schemes at airfields range from complex to relatively simple. Two items that each unloading scheme has in common are baggage trolleys and conveyor belt vehicles. While in use, passenger access ramps and baggage transfer equipment are parked near the aircraft, otherwise the ramps are retracted and the equipment parked out of the way.

Terminal buildings at large airfields are usually the most conspicuous structure found at the facility. The airfield terminal is usually crowded with aircraft due to

the arrival, departure, and movement of passenger aircraft on the terminal parking apron. Large capacity automotive parking lots, parking garages, and road/rail access, are features that make the terminal building at a large airfield easy to identify.

At medium and small airfields, the passenger terminal is far less spectacular than those found at larger airports. Small airport terminal buildings sometimes share floorspace with other offices and functions at the airfield, thus the building may be larger than expected.

The identifying characteristics of most small and medium airfield terminal buildings are:

1. an awning covered walkway leading to the aircraft parking apron with mobile air stairs serving the passenger aircraft.
2. small automobile parking lots with a loop drive way for taxi or bus passenger pickup.
3. a single baggage trolley and
4. a small illuminated passenger aircraft parking apron.

Passenger terminal facilities at smaller airfields are much more difficult to identify because of their lack of easily defined characteristics. In such cases, the presence of automobiles parked in a lot near a roofed structure and the presence of a nearby patio or smoking gazebo may be the only clues to the presence of a passenger terminal.

Figure 68: Passenger terminal and operations building at a small airfield.

Figure 69: Passenger terminal at a military airfield, note the covered walkway to the parking apron.

Heliports

Heliports are airfield facilities that are exclusively used for helicopter operations and are most often associated with military rotary wing aircraft. Some heliports are part of an existing airfield and share the airspace with fixed wing aircraft, while other heliports are specifically designed for helicopter use.

The Federal Aviation administration defines a heliport as: An area of land, water or a structure used or intended to be used for the landing and takeoff of helicopters and including any buildings or facilities.

There are two categories of military heliports, temporary facilities that serve forward deployed military helicopters in wartime, and permanent facilities that are constructed to support military helicopters in garrison.

At airfield facilities that handle both rotary wing (helicopters) and fixed wing aircraft, the helicopter parking and landing area is always separate from the rest of the airfield.

Helicopters do not need runways or taxiways to take off and land, however to maintain order and safe aircraft movement at the airfield, they follow the same traffic rules and procedures as fixed wing aircraft. Except for a few minor differences in appearance, a heliport has the same features found at fixed wing aircraft airfields. The feature that is most noticeably different in appearance at a heliport is the helicopter runway. Compared to fixed wing aircraft runways, the heliport runway is very wide and short. Because very little or no runway length is needed for helicopters to initiate a rolling start take off, the long runways needed for fixed wing aircraft are not necessary.

Helipads are small designated landing and parking areas for helicopters. Helipads usually have a prepared surface and are found in groups at heliports, and airports, or alone at various locations such as hospitals, police departments, office buildings and in military complexes. Worldwide, helipads are marked with several different symbols, however the most common marking is a large letter "H" that indicates the center of the landing pad.

Figure 70: Helicopter pad markings

Figure 56: Side view of an aircraft bunker

Photo Interpretation Training Course

Air Operations and Flight Control Facilities

The flying and supporting activities of an airfield are directed and coordinated from the operations building and control tower. These functions may be located together or separately in permanent structures, or in vans and trailers at small or temporary airfields.

Air Operations Buildings

Air operations buildings are usually located on the perimeter of the landing area, often along the parking apron. The building is likely to be small or medium-sized in comparison to the surrounding hangars and shops. At civilian airfields the management and air operations functions are usually conducted in one building referred to as the terminal building. At military airfields the operations building houses the pre-flight briefing room, weather office, flight planning publications room and aircrew lounge. The size and variety of services offered at either a civil or military facility will depend upon the amount and type of air traffic using the airfield.

Control Towers

Control towers frequently sit atop the operations building, along with radio masts, radar antennas, windsocks, and weather measuring equipment. Some control towers are stand alone structures that are set away from the operations building.

Figure 71: Air operations building and associated communications equipment

Photo Interpretation Training Course

Of the many functions performed by personnel in the control tower, their primary duties and responsibilities are:

1. Monitor, observe and direct air traffic on the ground to the appropriate runway or parking area.
2. Regulate use of the runways by inbound and outbound aircraft.
3. Ensure that aircraft are separated by sufficient distance to maintain safety.
4. Report runway and weather conditions to aircraft.

Airport control towers are normally metal or cement structures and are tall enough to observe all parts of the airfield where aircraft movement occurs. At air facilities that are spread out over a large area, auxiliary control towers are sometimes utilized to ensure that all aircraft movement areas are monitored and controlled.

Airport (Rotating) Beacons

The airport beacon is usually tower mounted, or installed upon the highest structure near the runway. The rotating beacon sends a color light signal that is visible up to 10 degrees above the horizon. It is used to indicate the

Figure 72: An airfield control tower at a military facility looks no different than one at a civilian airfield.

Figure 73: A rotating beacon located near a hangar at a civilian air facility

tiff-
ield.

Course

Figure 74: A joint use air facility with two control towers. Often several control towers will be used at large airfields or at joint airfields where ground operations/movement cannot be observed by one tower. A Surface Detection Radar unit is sometimes installed on top of the control tower and will appear as a large white dome.

presence and type of airport at that location. The beacon may be an omnidirectional flashing light or it may rotate at a constant speed that produces the visual effect of flashes at regular intervals.

Inland Waterways

Transportation by boat, barge or ship was man's first method of moving large quantities of people or supplies over long distances. Although roads and railways have largely supplanted ships for inland transportation, boats and barges are still widely used for transportation of bulk materials such as grain, coal and other non-perishable items. Although not as fast as other methods of transportation, shipping is still the least expensive.

Most inland water transportation is done by barges. There are two types of barges, the powered barges commonly used in Europe, and the unpowered barges (dumb barges) used in North America. In other parts of the world, one or both types may be used, in combination with various types of locally built boats. All are designed for use on inland waterways, where width and depth restrictions preclude the use of ocean-going craft.

Canals

Even with their narrow **beam** (width) and shallow **draft** (depth of hull below the waterline), barges require a minimum width of channel and depth of water in order to move freely. In addition the channel must be free of obstructions (rocks,

rapids, sandbars, tree stumps, etc.) and must have no sharp changes in course. In addition, the gradient of the waterway must be low, or the velocity of the current would preclude upstream movement, and make downstream movement hazardous. Only in the largest of natural waterways are these conditions met. Even in these, it is frequently necessary to dredge and clean the main channels to keep them clear for navigation.

Smaller waterways often require substantial modification to make them navigable. The course may be modified by straightening and rounding of curves. Shallow reaches may be dredged, or the depth of water may be increased using a combination of levees, dams and dredging. In areas with seasonal fluctuations in water level, additional modifications are needed to insure adequate water depth during the dry season. The greater the extent of the modifications, the less the **channelized river** resembles a natural watercourse. In some cases, difficult areas are bypassed entirely by construction of a short canal.

Figure 1: A channelized river

Sometimes it is necessary to dig an artificial watercourse to connect two navigable waterbodies. These **canals** enhance the movement of materials by providing access to a greater area without the need to transship cargo. Canals can also be found cutting across a large meander in a river to shorten the traveling distance.

Note: The term canal has been used to denote several types of artificial or modified waterways, including those used for irrigation or drainage. For this discussion, a canal is a watercourse expressly built or modified to accommodate shipping.

Because of the requirement for a low, even gradient, canals are almost exclusively found in areas of smooth, level terrain, such as coastal plains, deltas and marshes, and along river valleys in areas of higher relief. The cost of digging through or bridging over obstacles can be prohibitively high, so a canal will usually follow the low ground. Abrupt changes in the elevation of the watercourse are handled by the construction of locks or shiplifts to move vessels from one level to the other.

Characteristics of Canals

Canals and channelized rivers share many characteristics with other bodies of water. The water area is usually smooth and dark in color, except in certain combinations of sun and viewing angle, where the bright reflection is visible. (This reflection would only be seen in one image of a stereo pair.) Reflections from areas of disturbed water, such as the wakes of boats, will often be visible.

The surface is level and generally follows the lowest part of the valley. The difference between a natural and a channelized watercourse is gradational in nature, depending on the degree of improvements made. The decision to call such a watercourse natural or channelized should be tempered by the product specifications.

The artificial nature of canals, and to varying degrees, channelized rivers, is revealed by the straight to evenly curved alignment, the even width, and the regular shape and slope of the banks. Levees may be present as the canal passes through low areas, or it may be cut into the ground as its course deviates from the valley bottoms. Because of the even depth of water, the canal will exhibit a uniform dark tone, except occasionally in the shallows near the banks.

The presence of barges and other cargo vessels indicate that the waterway is used for transportation. Small pleasure craft may be found on many waterbodies not otherwise used for transportation, and the analyst should be careful not to confuse them with cargo vessels. The presence of one or more locks is the primary key in identifying a canal. When neither barges or locks are visible, look for high clearances under bridges or for moveable spans. In addition, the bridge pillars may be surrounded by barriers to protect them from damage by passing boats. These characteristics will aid in differentiating a canal from an aqueduct, ditch or non-navigable natural watercourse.

Figure 2: A canal as compared to an asphalt road

The dark, smooth surface of the water and the enhanced alignment of the canal may give it the appearance of an asphalt road. The presence of barges and locks, the absence of lane markings and the absence of connections to the rest of the road network help to identify the feature as a canal. In addition, canals are fairly wide when compared to roads. At least thirty meters is needed to allow two standard barges to pass.

Basins

Lay-by basins are found where a canal is so narrow that it will allow only one shipping lane. The canal bank is cut away at a convenient point to form an area of water where vessels can lay-by until traffic coming from the other direction has passed. These are analogous to passing tracks on single track railroads. Turning basins are areas on the channel or canal that have been enlarged to allow for the turning of vessels.

Figure 3: Examples of basins on an inland waterway. Note the turning/lay-by basin at the bottom of the right figure.

On larger waterways, loading and unloading facilities may be located directly along the banks, but frequently there are basins cut into the banks to bring the barges out of the main channel and closer to the facilities they serve. These are analogous to railroad sidings.

Locks

A lock is a narrow rectangular basin used for the raising and lowering of vessels between water bodies at different elevations. A ship enters the lock through gates at either end, and then water is either pumped into or out of the lock to bring it level with the other water body. On waterways with a high volume of traffic, locks may be paired to accommodate traffic moving in both directions.

Lock widths and lengths will vary depending on the size of the vessels expected to use the canal. Most are between 17 and 33 meters in width and the usable length is anywhere between 120 and 370 meters. The vertical lift distance varies from one meter in some tidal canals to over 30 meters in major rivers such as the Columbia and the Snake.

Figure 4: A single lock with miter gates. Upstream is toward the bottom of the figure.

The locks are usually made of concrete and will appear white in tone. The lock gates are usually metal and will have a darker tone. In addition, some of the mechanisms for opening and closing the gates will be visible, as well as a control building. Often there will be a guide wall before and after the lock on rivers.

Several different types of gates may be used on locks. The most common is the **miter gate**, a two-piece gate that, when closed, forms a "V" pointing upstream. This configuration uses the upstream water pressure to hold the gates closed. (The analyst can often

Figure 5: Twin locks with miter gates. As in the previous figure, upstream is toward the bottom.

Figure 6: Five types of lock gates shown in the closed (left) and open (right) positions.

use miter gates to determine the direction of flow in a watercourse.) Other types of gates include **vertical lift**, **tainter**, **sliding caisson** and **shaft gates**.

Where rivers and canals connect to the sea, there may be a substantial tidal variation in water depth. To accommodate these changes, and maintain a navigable water depth in the waterway, tidal locks are constructed. If the **tidal locks** have miter gates, they can be identified by the fact that the gates point outward from the lock at both ends, instead of in the same direction. If other types of gates are used, only the lock's position near a coastline would indicate that it is a tidal lock.

Figure 7: Tidal lock

Dams and weirs are often constructed on rivers or canals to maintain navigable water depth, to reduce gradient and current velocity, for flood control, or to impound water for irrigation or other uses. In

Figure 8: A single miter lock used to bypass a low dam

Figure 9: A thrust basin

these areas, the locks are used to allow ships access past the dams. If the change in elevation is large, a series or **flight** of locks may be required. In other cases, locks are used along canals connecting waterbodies at different elevations.

Basins are often built parallel to the lock chambers to use for water storage (thrift basins) in areas where an adequate water supply is not available, or for use as lay-by or turning basins.

Shiplift

A **shiplift**, like a lock, is a structure which moves ships between waterbodies at different elevations. A ship will maneuver into a water-tight tank-like basin with gates at both ends. The entire basin is then raised or lowered like an elevator.

The mechanism may be either mechanically or hydraulically operated. Shiplifts are used in locations

where there is a substantial change in elevation, and construction and operation of a shiplift is more economical than a flight of locks. They may also be used where there is an insufficient supply of water to operate a lock.

Figure 10: A side lift shiplift

Figure 11: A front lift shiplift

Figure 12: A front lift shiplift being used to lower a vessel.

A shiplift will be large enough to hold one ship only, usually thirty to forty meters long. Shiplifts consist of a light-toned concrete base upon which the steel truss framework for the lifting mechanism is built. The large size of these structures, as well as their position in between waterbodies of differing elevation makes them easy to identify.

Gates

A **sluice gate** is a gate, not associated with a dam, used to regulate the flow or level of water, whereas a **weir** is a fixed structure with the same purpose. They can be found on both navigable and non-navigable waterways. Along coastal areas, tidal sluice gates are used to maintain a suitable water depth in basins and canals during periods of low tide, or to protect areas from inundation during high tides. On navigable waterways, locks are used to bypass the sluice gates.

Figure 65: Jet Engine Test Cell

Photo Interpretation Training Course

Transportation

Cultural Features 165

Figure 13: Safety gates

Safety gates seal off a section of a waterway in the event of a breach. They are most frequently found near an intersection with another waterway. The most common type of safety gates are large plate-girders suspended in a massive superstructure. They may operate either on the guillotine principle, where the plate girder is dropped into place, or the entire girder and supporting structure can be lowered into the water. Their massive construction makes them easy to identify from the air.

Terminals

Inland waterways generally do not have large port facilities, such as those associated with maritime shipping. Cargo is normally loaded and unloaded from individual facilities, either directly on the watercourse, or in a basin attached to it.

The historical reliance on shipping for transportation led to the construction of many industries along inland waterways. Therefore, those that still rely on barges for delivery of raw materials are ideally situated to have the materials delivered directly. Since raw materials are not so conveniently located, they must be delivered to a transshipment facility by truck, train or pipeline. Some materials, such as refined petroleum products, are also delivered to transshipment points for distribution to users not located near the watercourse.

These terminal facilities can be identified by the presence of moored barges, conveyors, cranes or other cargo handling equipment and storage facilities.

Photo Interpretation Training Course

Figure 66: Cargo handling facility

On the airstrip side of the cargo handling facility, the parking apron is illuminated by apron floodlights, and is occupied by various handling vehicles such as forklifts, tow motors and trailers. Aircraft being loaded/unloaded are not always present on the cargo parking apron when it is observed. When not actively engaged in loading cargo aircraft, the transfer vehicles and handling equipment are usually parked on the apron's edge or inside of the warehouse structure.

Chapter 3

166 Cultural Features

Figure 14: Some of the various types of cargo handling equipment found at inland waterway terminals.

The storage facilities may consist of tanks, elevators, warehouses or open storage areas. If the materials are being transhipped, a rail or truck loading/unloading facility will also be present.

PORTS AND HARBORS

General

Ports

Ports are settlements with installations for handling waterborne shipping. Principle port facilities consist of berthing space, storage space, cargo-handling equipment, cargo transshipment facilities, and vessel-servicing facilities. Ports are classified on an area-wide rather than a worldwide basis. Mearing, a principal port in a small maritime nation may be equivalent to a minor port in the more extensive port system of another country. In wartime, principle and secondary ports and bases are prime targets for destruction, and the relative importance of minor ports increases.

enough space to accommodate large numbers of vessels, and a shoreline that can be developed as a port and as a site for industry. Harbors may be situated on the sea, estuaries, or inland lakes and rivers and may easily be recognized by abundant waterborne traffic and port facilities.

A natural harbor is one that can be used without harbor works or improvements of any kind. Relatively few strategically located natural harbors are large enough or safe enough to be valuable to shipping. The improved natural harbor is one

Photo Interpretation Training Course

whose utility has been enhanced by the addition of artificial works and improvements. The artificial harbor is one that is created and maintained largely or entirely by human efforts. Many of the important harbors of the world are man-made.

Harbor Works

Harbor works, including protective works, are the structures designed to provide shelter, to control water flow, and to regulate erosion for the improvement of the navigability of a harbor. The principal categories and types of structures are; breakwaters, jetties, groins, sea walls, bulkheads, dikes, locks, and moles. Harbor works do not include port facilities that are designed specifically for the transfer of cargo and servicing of vessels.

Breakwaters

Breakwaters are structures protecting a harbor or beach from the forces of the sea. They may be located on the seaward boundaries of a harbor or can be located within the harbor itself. They may also be located just offshore, protecting the harbor or possibly a beach. If the breakwater is connected to the land, it is called peninsular, if it is entirely offshore, it is called insular.

Breakwaters are narrow, linear structures that extend across or at an angle to the entrance of a harbor or appear as linear offshore features. If a portion of the length of the breakwater is above the water's surface while

the remainder extends underwater, the end of the exposed portion could appear to be pointed due to the angle of the feature and the water's surface. The "point" will be towards the underwater section.

When a portion of the breakwater is not wet it will generally have light tones on an aerial photo, but darkens when it becomes wet. Careful examination of the texture will assist the analyst in determining the material composition. One

Figure 3: Aerial view of insular and peninsular breakwaters

Figure 4: Cross sections of two breakwaters of different construction materials

made from rock will be relatively rough, while a masonry breakwater will have smooth edges.

An observer may actually see how the breakwater works by paying attention to the surface wave patterns. The breakwater will considerably dampen wave propagation with calmer water in the harbor.

Mole

A mole is a massive breakwater (tens of meters in width) with freight transfer facilities on it. A mole is constructed on the seaward side of a harbor and is not necessarily connected to the shore (insular). The mole is used for its protection against current and wave action, drifting ice, sanding up, and winds just as a breakwater does. Moles are large enough to accommodate freight transfer equipment that is part of a wharf or along a quay wall. They usually have roads or even railroads on them if the feature is in a peninsular position.

Figure 5: Mole diagram

Transportation

Cultural Features 171

Figure 7: Two jetties (a) where a river empties into a body of water. Note also the POL bunkering piers (b) and POL storage tanks (c) on the left side of the picture.

Jetty

A **jetty** is a solid linear structure of stone, concrete or other material that projects out at an angle from the shore. Jetties are usually found in pairs, and are located at the entrance of a harbor or the mouth of a river. Their purpose is to restrain or control the direction of currents and to maintain the channel opening and depth from silting. Commonly, a light is placed at the end of the jetty out in the water for safe navigation. This feature looks similar to a breakwater, but its location is a key to identify it as a jetty.

As mentioned, jetties are usually found where a river empties into a body of water (see Figure 7). This will give the appearance of the river extending into the open water. Jetties are long narrow linear features exhibiting light

Figure 8: Examples of how a jetty may be used where two watercourses intersect

tones when made of masonry or concrete, however, it will appear darker in tone when wet. If the construction material is rock, then the tone is usually darker. The perception of texture will be dependent on the scale of the photos. One comprised of rocky material will be relatively rough while the jetty

Photo Interpretation Training Course

composed of masonry or concrete will be smooth and may have a sharp edge if a wall is present.

Jetties may be found when two watercourses intersect in an area that has been built-up. In some of these situations, the jetty may form the side of a tidal basin.

Groin (Gryone)

This structure (usually one of a group) extends usually perpendicular from a shore to protect the shore from erosion by tides, currents, or waves or to trap sand for making a beach. The resulting pattern may give the shoreline a sawtooth or scalloped appearance because of sand being deposited on one side of the structure. Groins are found along coastal shorelines, or along the banks of inland waterways.

Figure 9: A series of groins along a shoreline. Note the build-up of sediment on the side of the groin which is down current.

Training Wall

The training wall is a structure built along a channel in order to direct the stream or currents through the channel. This funneling of the water movement helps to increase the current thus promote a scouring action to keep the channel from silting up. During high water, training walls are often submerged. On the down stream side of the walls, sediment accumulates and eventually a sawtooth or scalloped appearance of the channel shoreline appears just as with a groin.

Figure 10: These groins (training walls) are placed along a channel to increase the speed of the current thus, reducing the amount of deposition in the main channel

Sea Wall

This is a structure built along the shoreline to protect the shore from erosional forces. The sea wall is a long linear feature that is only a couple of meters wide. They are constructed of concrete, rubble, or masonry and will usually exhibit a bright photographic tone. The sea wall is constructed at varying locations on the shore. It may be right at the land-water interface always protecting the shoreline from the sea or it could be built on the shore for protection during high tide or during storm surges (Figure 12). In this case, when viewing aerial photos, the sea wall will usually appear as a light toned linear feature up on the beach away from the land-water interface.

The sea wall should not be confused with what is known as a quay wall, that is used for berthing of vessels. Quay walls are covered in a later section. Another feature that

Figure 11: Seawall construction

Figure 12: On the left is a seawall as a solid linear feature currently at the land-water interface and on the right the seawall is onshore for protection at high tide or during storm surges

acts similar to a sea wall is the bulkhead. The difference is that a bulkhead is constructed of piles or sheet metal erected vertically along the shoreline.

Berthing Facilities

A variety of berthing facilities are used within the modern port. Each is designed for a specific purpose. The purpose of the vessel's visit and/or the nature of the cargo will determine the type of berthing facilities.

Figure 13: Bulkheads

Berthing Buoys

Berthing buoys, or mooring buoys, are provided in harbors where space restrictions prohibit free-swinging anchorage, where the number of accommodations is limited, and as a more secure berth than can be provided by a ship's own anchors.

Several types of berths can be provided by mooring buoys: a) free-swinging (one buoy), ship's head secured to buoy, b) bow and stern (one buoy), ship secured ahead by own anchors and astern to buoy, or ship secured ahead to buoy and astern to bollards ashore, c) bow and stern (two buoys), ship secured to buoys ahead and astern. Buoys may be held by a single anchor, but generally, two or more anchors laid at varying angles are used for greater holding capacity and more precise positioning of the buoy. When more than one anchor is employed each may connect independently with the buoy. However, ground chains from each anchor converging at a heavy sinker and secured by a pendant chain is more common.

Mooring buoys (particularly those used by naval craft) may be fitted with submarine cable connections for telephone, electricity, and water.

Mooring buoys vary in design depending on their intended use. On aerial photos, the resulting shapes may range from simple circles to that of a four-leaf clover, all of which vary in size up to several meters across.

Figure 14: Berthing or mooring buoys

Figure 15: Mediterranean mooring

Fixed Moorings

Mediterranean Moorings

Ships may lie in fixed moorings without buoys in a variety of ways. The simplest method is that of mooring with one or both anchors ahead and stern lines to bollards ashore. This is used where facilities are limited, and is commonly employed in Mediterranean ports. With the Mediterranean moorings, ships lay stern to and off at right angles to a quay wall or wharf.

Dolphins

Dolphin moorings usually consist of a group of posts lashed together at the top, measuring around one to three meters (3-10 feet) across. Dolphins are located off the shore and are used singly for breasting into or hauling out of a berth, and in a series for mooring a ship fore and aft alongside. They conserve space in a stream and are used either for idle berthing or for working cargo by lighter. Dolphins are often associated with a wharf either as a protective device at a wharf's corner and face, or as means of increasing the length of berthing space provided by a wharf face. Dolphins are usually cylindrical or square shaped and will exhibit a light tone, in contrast to the much darker tone of the surrounding water.

Figure 16: Different styles of dolphins

Figure 17: Dolphins extending the berthing space of a wharf

Figure 18: Dolphins at a ferry landing slip

Figure 11: A front lift ship lift

Photo Interpretation Training Course

Transportation

Cultural Features 177

Piling

Another type of mooring device is the piling that consists of just a single post. These are much smaller than the dolphin and would be utilized by smaller boats.

Figure 19: Piling or post

Bollard

A bollard is a post (usually steel or reinforced concrete) firmly secured on a pier, wharf, quay, etc., for mooring vessels by means of lines extending from the vessel and secured to the post. They are usually a meter (3 feet) or less in diameter, and are difficult to discern on all but very large scale imagery. However, they may be located when a vessel is docked and the securing lines are visible leading to the shore. It is at this location on the wharf or quay where the bollard is located. Bollards are usually not shown on charts.

Figure 20: Bollards as they may appear on a wharf and pier.

Piers/Wharves

The majority of landing structures are either piers or wharves, and are defined as berthing places for vessels or decks for land based recreation. Piers project into the water at an angle to the shoreline. Berthage is usually available on both sides of the pier and at the head as well if the structure is wide enough. Variations of the simple straight pier are the T-head pier and the L-head pier, which are commonly used to transfer bulk petroleum, and berthage is generally confined to the pier head.

Photo Interpretation Training Course

Figure 21: Three types of piers

Wharves form the pivot point for port operations, and detailed information concerning them is necessary to evaluate a port's capabilities. Generally, the term wharf includes all landing structures, even piers. Specifically, a wharf is a structure that parallels the shoreline and provides berthage at its face only. Wharf design is determined largely by its intended use and by local conditions and engineering practices. Variations in the names of landing structures cause considerable confusion, and analysts should be careful to use the proper term. The term dock is properly used in northwestern European countries to designate a water area; in the U.S., however, it is applied generally, but erroneously to any type of landing structure. The pier structure is commonly called a jetty in British and other foreign ports, and all marginal structures are called quays.

The wharf is classified as marginal, quay, or offshore. The marginal wharf and quay are both built parallel to and against the shore and differ only in construction type.

Figure 22: Pier, wharf, quay wall comparison

Figure 23: Wharf examples

The marginal wharf is constructed on pilings over the water and is in a peninsular position to the shore. The quay is a solid wall of masonry or other material and is back-filled with earth. The offshore wharf is a structure of open pilings built parallel to but in an insular position off the shoreline. It may be connected with the shore by one or more approaches, gangways, or pipelines. A variation of the offshore wharf commonly used in the Far East is the pontoon wharf, which consists of pontoons of various constructions moored in a fixed position offshore and connected with the shore by one or more adjustable gangways. This type is used where the water level fluctuates considerably.

Two special wharf types are the mooring platform and the breasting platform. The mooring platform is a small offshore wharf with a square platform or deck. It provides berthage for a ship but is too small for cargo transfer. Mooring platforms commonly are provided in groups of two or more, and ships are berthed across the heads. One or more of the mooring platforms is generally connected

with the shore by a narrow approach or trestle, and platforms may be connected by catwalks. The breasting platform is a small platform structure projecting from the face of the wharf bulkhead. Breasting platforms are usually provided in groups of two or more, and ships are berthed across the heads.

Wharf construction and materials vary greatly, however, most structures are either open or solid construction. Open construction is used for marginal wharves, off-shore wharves, and most piers. In its simplest and least permanent form, it consists of open-spaced wooden pilings supporting a wooden deck. Variations of design are numerous and contribute to the strength and permanence of the open structures. Substructures may consist of steel or precast concrete pilings. The superstructure or decking may vary from wooden joists and flooring to concrete and steel construction with an asphalt or other paved surface.

These different construction materials will create a variety of tones associated with the wharves or piers. The wooden deck has a tonal signature of light to medium gray where a deck constructed of concrete will generally have light tones. The asphalt or steel surfaces will be medium to dark gray, almost black in some cases. Piers and wharves used as a transfer point of freight can exhibit an array of tones due to cargo, cargo handling equipment, buildings, roads and railroads, etc., all on the deck of the wharf or pier.

Recreational Piers

Some piers are used for recreational purposes such as for pleasure craft and will be very narrow compared to their lengths. This type of pier usually has a deck constructed of wood or even aluminum. The aluminum will give off very light tones with the wood surface having light to medium tones. When grouped together with other facilities for small boats the location can be referred to as a marina. Promenade piers are used for leisurely, non-boating activities and may have buildings on them and possible even amusement park attractions on the pier.

This category of pier/wharf will typically be found away from industrial and cargo handling port areas and will be in marinas or along open shoreline. Usually, there is a repeating pattern of piers paralleling one another in a marina (Figure 25). Some associated features include recreational boats docked along the

Figure 24: Mole (a breakwater that also has a wharf on it with a road or even a railroad)

Figure 25: Recreational piers

pier, exhibiting near white tones and nearly uniform sizes and shapes, ramps for off-loading and retrieval of boats, or a parking lot with vehicles, some with trailers attached to them.

POL Bunkering Pier

POL (Petroleum, Oil, and Lubricants) bunkering piers are large elaborate pier structures of varying shapes, equipped with facilities for loading and unloading of liquid cargo (usually crude oil or other petroleum products). Most of these oil bunkering piers are characterized by their extreme narrowness in comparison to wide dry cargo piers. This is because there is no need for temporary storage and handling areas.

The piers may be constructed using a modified T-head pier or may be constructed offshore and served by a submarine pipeline. In both cases, the pipelines from shore usually have their origin in a nearby petroleum complex or storage tanks. The unique construction of these types of piers can easily be recognized, as illustrated in Figure 27. The offshore POL bunkering pier, sometimes referred to as an offshore loading facility, usually has the capability to accommodate two vessels simultaneously.

Figure 26: POL bunkering pier. See also figure 7.

Figure 27: Two different styles of the POL bunkering pier. See also figure 7.

Figure 28: Offshore loading facility

Terminal Buoy

Another type of offshore facility which transfers cargo is the single point mooring (*terminal buoy*), which is much smaller than a POL berth. The terminal buoy is, as its name implies, a buoy, and is charted as such. The terminal buoy may have a variety of shapes and is substantially larger than the standard mooring buoy. It is positioned offshore in deep water with three or more chains attached to heavy anchors.

The terminal buoy has a revolving platform or swivel to which the tanker is secured as are the floating hose lines for cargo, bunker oil, and fresh water. The buoy's flexible hoses are coupled to the ship's system, permitting ship and hose lines to swing together a full 360 degrees with the wind or sea. Product transfer is conducted through submarine pipelines connecting the buoy and a shore installation. An ancillary source should be used to identify it as a single point mooring.

Quays

A quay is a structure of solid construction along a shore or bank, which provides berthing and normally cargo handling facilities as well. It consists of a retaining wall with solid backfill, covered with a surfaced decking. A quay wall may be a simple facing of interlocking sheet steel piling, a monolithic concrete wall, or a masonry structure built of stone or precast concrete blocks. Many quays abroad consist of large concrete caissons sunk in-line to form a wall, then back-filled with concrete or rubble and capped with a reinforced concrete deck.

Figure 29: Quay wall construction

Basins

Basins are artificial, partially enclosed bodies of water that form a harbor or part of a harbor for the purpose of berthing vessels. They are usually bordered by wharf structures or quays. Gates or caissons may be constructed at the entrance, or at each end, to control the water level inside.

Tidal Basin

A tidal basin is a partially enclosed body of water that is affected by tidal influence. Vessels berthed within a tidal basin rise and fall with the tide, thus creating a problem for the transfer of cargo. Tidal basins are open to the sea, and have no structures to allow them to be closed off.

Figure 30: Three types of basins found in ports.

Half-tide Basin

A half-tide basin is a lock large enough to handle freighters (which usually range in size of 75 to 150 meters (250 to 500 feet) in length). It operates with gates, which are kept open for several hours after high tide so that vessels may enter as long as there is sufficient depth over the sill. Vessels remain in the half-tide basin until the ensuing flood tide before they may pass through the gate to the inner harbor or wet dock that has quay walls along the boundary. If entry to the inner harbor is required before this time, water must be admitted to the half-tide basin from some external source. Owing to the enormous amount of water required to raise the water level it cannot be used at all states of the tide; hence its name, half-tide basin.

Wet Dock

The third type of basin is called a wet dock, or non-tidal basin, which is also a controlled level basin like the half-tide. This enclosed basin is separated from tidal water by a miter gate. Usually, ships are moved into the dock near high tide and the gates are closed when the tide begins to fall to maintain the water level.

Photo Interpretation Training Course

Transportation

Cultural Features 185

If necessary, ships are kept afloat by pumping water into the dock to maintain the desired level. A difference between a half-tide basin and a wet dock is that a wet dock allows vessels to pass in or out of the basin during any phase of the tide.

It should be mentioned that basins are not restricted to coastal harbors. They can also be found along water courses or inland shorelines.

Figure 31: Basins along a river

Ramps

Ramps are partially submerged hard surfaced areas on a shoreline for launching and retrieving vessels or vehicles. They are primarily used in harbors near recreation piers. They usually are at the edge of a parking lot (small or large) and are identified on aerial photographs by the notch created by them in the improved shoreline. Ramps located outside of harbors are more difficult to identify, but can be located by searching for the hardened pad of the ramp.

Figure 32: Ramps located in a marina.

This pad is constructed usually of concrete and will have a brighter return than the adjacent ground or parking area. The submerged portion of the ramp is usually visible because of the shallow water.

Cargo Handling Equipment

Cargo berthing space may be recognized by the presence of heavy handling equipment located on piers or wharves. However, very small ports may not have any such equipment, requiring vessels to supply and use their own. The equipment used for the movement of freight varies from manual labor to large cranes specifically designed for handling crates, containers, and heavy equipment.

Figure 33: Gantry and transporter cranes

The variety of cranes is large and it is difficult to classify them systematically. Likewise, terminology dealing with cranes differs greatly due to the variation in local and national technical terms. Cranes can be classified either on a basis of function or generic type. The generic types of gantry, transporter, cantilever, jib, floating, derrick, and shearleg cranes will be discussed next.

Gantry Cranes

A gantry crane is a traveling crane on rails that consists of a hoist on a heavy cross girder, called a bridge, which is supported at two points. Hoisting is performed by a trolley or cab that moves transversely along the bridge. Gantry cranes occasionally serve as a base for a jib crane, the latter being mounted on and capable of transverse movement along the bridge member. Gantry cranes are used extensively in shipyards for hull erection and in various industrial yards and shops for heavy lifting. They are usually electrically operated. Depending on use, they may range up to 250 tons capacity. Hoisting capacity is constant regardless of the position of the cab or trolley on the bridge. Gantry cranes are sometimes referred to as "bridge cranes." An overhead crane differs from a gantry crane in that the supporting mechanisms do not move as they do on the gantry.

Transporters are cranes characterized by a long beam (bridge) of relatively light construction, supported by one or more vertical uprights, or towers. There are two types of transporters. The bridge transporter is similar to the gantry crane, but it is of light construction. The tower transporter has a bridge that is supported by a central tower. This type of transporter is usually located on a narrow pier. In both cases the crane is constructed so that it may travel beyond each supporting leg. They are normally used for handling loose materials such as coal or ores.

Cantilever Cranes

A cantilever crane consists of a base or tower structure on which is mounted a counter balanced, horizontal arm or jib. There is a trolley that can be racked along rails on the cantilevered jib that carries the hoisting sheaves. The trolley does not carry the hoisting mechanism but merely serves to support the fall, and its transverse movement is controlled by a system of sheaves and ropes. The entire machine may be mounted on rails for movement along the pier or wharf.

Cantilever cranes are most commonly found in shipyards, although they may be used for cargo handling in special instances where a large working radius is required. They are normally electrically powered and range up to 250 tons or more in capacity. There are three types of cantilevers. The giant hammerhead has a fixed base and is usually located at fitting-out basins in shipyards. Titans have low bases and are relatively rare. Third, is the tower cantilever that resembles a tower jib crane. The difference between these two is that the tower cantilever's arm is horizontal and the tower jib crane has the arms extending out an angle.

Figure 34: Cantilever cranes

Jib Cranes

A jib crane consists of the primary arm on which is mounted a shorter arm, or jib, extending at an angle. At the end of the jib are sheaves, which the fall runs through and where the load is suspended. The fall is raised and lowered by a hoisting mechanism built into the crane. Jib cranes are frequently mounted on gantry, bridge, or trestle bases, where they are capable of transverse movement. Because of their versatility, they are the most common cranes and have a wide range of uses. Various forms of the jib crane are common along wharves for handling general cargo and also for vessel construction in shipyards. They are usually electrically powered and range in capacity from 3 to 5 tons, but may have capacities of 100 tons or more.

Floating Cranes

A floating crane is almost any crane mounted on pontoons or barges. The float may range from a simple wooden barge to an elaborately constructed steel hull with built-in balancing tanks and pumps.

Figure 35: Floating cranes

Figure 36: Types of jib cranes

Large floating cranes are commonly used in harbor construction, salvage operations, or transfer of heavy cargo to and from ships. Capacity may exceed 400 tons in some cases. Small floating cranes are driven by internal combustion engines or operated manually and are used for many lifting tasks.

Derricks

Derricks consist of a vertical mast supporting a pivoting jib or boom and appear as a maze of braces and masts on aerial photography. The mast may be stayed by cables or beams anchored to the ground, with the fall running through sheaves at the end of the jib. Large derricks are used for miscellaneous heavy-lifting tasks and run on steam, gasoline, diesel, or electricity. Small derricks are used for simple cargo handling and are operated manually or are driven by gasoline or diesel engines. Derricks and shearlegs are the simplest and least expensive cranes. Depending on size and type, capacity may range from 1 to 40 tons.

Figure 37: Derrick type crane

Shearleg Cranes

A shearleg crane is a fixed hoisting device with a leaning tripod supporting the system of pulleys and cables. Heavy shearlegs may range up to 150 tons capacity. In hoisting and lifting motions, the operating dimensions are comparable to those of the jib crane.

Figure 38: A shearleg crane

Ship Yards

Maritime shipyards are located at protected harbors or estuaries, both of which must possess a sufficient depth to accommodate the ships launched or repaired. Inland shipyards usually produce and repair smaller vessels for use on rivers or lakes, but may also construct submarines. Boat yards producing smaller craft, both maritime and inland, can be located at any protected waterfront. Some of these yards are capable of building small, high speed naval craft.

Slipways

Shipbuilding yards are recognized primarily by the presence of slipways, sometimes just called "ways." It is rare to find a single slipway; they are usually built in groups of at least three and may number over ten in a series along the

Figure 39: Layout of a large shipyard and how it may appear on aerial photos.

shore. Associated with slipways are huge steel frameworks and traveling cranes for handling the steel girders and plates. The majority of slipways are situated so that the completed vessel can be slid stern first into the water. The slipway is constructed with one end near ground level sloping down to the other end and into the water. This inclined bottom has an inclined rail (groundway), or a keelway leading from the head of the way, down into the water. It is this inclined bottom that helps identify the slipway and differentiate it from the drydock. The dimension of the area within a single set of frames limits the size of the vessels that may be constructed in the slipway. Occasionally two small vessels are built in a single slipway.

Slipways for submarines can be specially designed, narrow and have relatively low framed covered structures, or may be the standard slipway modified with the additions of two parallel keelways, one on either side of the regular keelway. In this manner, several submarines, depending upon their class, may be under construction in a single slipway.

Slipways may be more difficult to find in a military shipyard, because the slipway could have a structure over the entire length or just over portions of the vessel. This is done to prevent observation of the vessels within.

Figure 40: Slipway diagram showing the inclined surface

Ship Yard Shops

The essential operations in shipbuilding are: design and layout, fabrication, assembly, erection, launching, fitting-out, and engineering. Design and layout (drawing of detailed lines of the entire ship's hull and preparation of full-size templates of all structural parts of the ship) are done in a large, low rectangular building in well-lighted areas usually referred to as a mold loft. The mold loft is close to or built as a second story to the fabrication shop. The fabrication shop (cutting, drilling, punching, and forming steel plates to the size and shape of templates) is in a large, long rectangular factory-type building, usually the largest in the yard.

Launching is accomplished by sliding the hull of a ship from the slipway into the water with little of the superstructure and interior completed. This is done to clear the limited slipway area as soon as the hulls are seaworthy. The unfinished vessels are placed in a fitting-out basin or dock where they are completed. Fitting-out basins may be differentiated from cargo handling docks, by the variety of cranes, heavy handling equipment, and material shops and buildings present. Submarines are finished in fitting-out docks just as any other vessel. These docks, however, are often covered with a shed-like roof projecting out from the wharf and are called "screened docks." Yards designed for repair only have no mold lofts or building ways, but usually have marine railways for hauling small craft out of the water and/or graving docks or floating dry docks. A great deal of shipyard work is done in the open, and outdoor cranes of various types are conspicuous.

The raw materials for ship building consist of large quantities of steel plates, which are normally visible outside of the fabrication shop. Pipes, steel objects in a variety of shapes, large castings, lumber, and various types of ship equipment are visible. This type of industrial activity requires a large labor force consisting of many skilled workers as well as manual laborers.

Although the primary design of this facility is to build or repair ships, other types of products may be produced including dredges, cranes, floating drydocks, prefabricated houses, and a variety of small metal articles. Less frequently, rolling mills, hydraulic pumps, tractors, tanks, locomotives, and other heavy machinery are manufactured here.

Vessel Storage And Repair Facilities

Since there is a time lag between the unloading and reloading of a vessel, one area of the port that is removed from the main traffic lane is designated for the temporary storage of vessels. It may be part of the port complex or it may be located along a river bank next to the port complex when the port is on an inland waterway. Vessels are usually moored side by side and give a photo impression of a concentrated grouping of vessels in contrast with rest of the port area.

When repair facilities are present, they are frequently collocated with the storage facilities. Repair facilities are identified by marine railways, floating drydocks and graving docks (often called drydocks). In all of these facilities, the hull of the vessel can be exposed to accomplish the repairs.

Floating Drydock

Floating drydocks are large U-shaped structure of one or more sections, which can be partially submerged by controlled flooding of its hollow walls and base to receive a vessel. The floating drydock is raised by pumping out the water so that the vessel's hull can be exposed for repairs.

This type of drydock is not permanently attached to the shore and is out in the water. When no ships are in it and it has not been lowered to receive a vessel, the floating drydock is easily recognized on aerial photos by its rectangular shape and the high side walls rising up out of the water. If it is submerged, only the two long rectangular walls and gates would be visible. When there is a ship in the facility having repairs done, the side walls are parallel to

Figure 41: Floating drydock with a vessel in it

Figure 42: Plan view and a profile view of an empty floating drydock

and are much narrower than the vessel. On aerial photos, the vessel will usually overshadow the floating drydock making identification more difficult. Therefore, one must carefully analyze the vessels in a port for this feature. Also, look for the presence of cranes capable of traveling on tracks mounted on the walls of the floating drydock.

These types of drydocks are portable and therefore can be located anywhere, not just in a harbor.

Drydocks

A drydock, also called a graving dock, consists of an artificial basin fitted with a gate or caisson, into which vessels can be floated and the water pumped out to expose the vessel's bottom. The term "graving" is derived from the process of burning barnacles and other accretions from a ship's bottom.

This massive structure, is part of the repair facilities in a port situated along coastal shoreline, inland shoreline, or river banks

Figure 43: A floating drydock with a vessel in for repairs

Figure 44: Drydock: (a) water has been pumped out. b) drydock is flooded.

and is constructed in the ground along the waterfront or off the end of a pier. The elongated shaped basin will vary in size depending on the port and the size of vessels to be repaired there. A drydock built to accommodate super tankers can be many hundreds of meters in length. When the drydock is void of water, the construction material may be determined from the tonal signature. Concrete and masonry material will have medium to dark gray tones. These materials can appear darker than normal due to the location in an industrial area. Any steel construction of drydock will exhibit very dark gray tones. If it is filled with water, with a vessel in it or not, the feature will generally have the same tones as the water just outside the gates.

The biggest clue to identifying drydocks is that they will appear as **depressions** along a shoreline. The top of this feature is at ground level, so any shadow of the drydock and most features within it appear in the interior of the drydock.

Figure 45: Graving dock

Other features that may help identify this are the presence of ships appearing out of the water onshore, cranes near and over the drydock, piers, wharves, etc. This feature may be confused with a slipway, but remember, a drydock has a level bottom and the slipway bottom is inclined starting from the surface farthest from the water.

Marine Railways

Marine railways are a single set of rail tracks or a parallel grouping of tracks that run perpendicular to the shoreline and extend from a point on shore down into the water. Overhead crane structures are usually present next to the marine railways. The facility consists of the tracks, cradles, and a winding mechanism for hauling vessels out of the water, so the bottom can be exposed. There are two types of marine railways, the end haul and the side haul. The end haul has the vessel approach the railway perpendicular to the shoreline and then the vessel is captured in the cradle and hauled onto shore (Figure 47). The side haul works by having the vessel parallel to the shoreline where it is captured on the cradle(s) and brought onto the shore. At this point the vessel is perpendicular to the tracks. In British terminology, the marine railway is called a *patent slip*.

When identifying this feature, look for the presence of a smooth concrete, masonry, or earthen surface, rectangular in shape, sloping down into the water. This surface is usually more square with side haul types and elongated with the end haul version. There will be a series of dark parallel lines on this smooth surface, these are the actual rails. One might be able to see the cradles and winch houses onshore. One obvious identifier in locating a marine railway is when a vessel is up out of the water. Marine railways are located in ports, shipyards, along inland shores, or rivers and associated with small vessel repair facilities.

Do not confuse this feature with a graving dock or a slipway. Remember, the marine railway is **not** below ground level.

Figure 46: The marine railway as part of a small vessel repair facility.

Figure 47: Side haul and an end haul marine railway

Figure 48: A vessel being hauled up onto the shore by way of a marine railway.

Figure 49: Ship Lift. This lift can also be used to raise vessels up to a level above the water, then hauled into a repair area.

Gridiron

Gridirons, or scrubbing grids, are the simplest of the repair facilities in construction and lack the associated heavy equipment. A gridiron consists of a flat frame, usually of parallel timber balks, erected on the foreshore so that a small vessel may dry out for repair or painting at low tide. The name comes from the fact that the timber beams are arranged such that they form a gridiron (network of crossing straight lines) pattern.

The operation of this feature utilizes the ocean's tides to place the small vessel on the gridiron. At high tide the vessel is maneuvered over the structure and held

Figure 50: *Gridiron*

in place. As the water recedes, the vessel is lowered onto the gridiron. Not a common feature, the gridiron may be found on the foreshore near a fishing village or small harbor. The tonal signature is medium to dark gray. Identification is easier when the gridiron is occupied by a boat. The presence of a boat out of the water and a structure underneath it helps to identify this feature. Note, there are no railways associated with this feature.

Military (Ports and Harbors)

Naval Bases

Naval installations are designed to support and further the mission of sea-going vessels, provide personnel training, support communications, contain repair facilities, and handle logistics support. Naval installations are the most fixed of the military installations, because they must be situated where the critical anchorages and channels for the navigation of warships are available. In addition, the necessary piers, drydocks, marine railways, shops and other repair facilities are usually of such permanence that moving them would be impossible. Because of its waterfront location, a naval base is seldom confused with army or air bases. It is often easy, however, to confuse naval bases with commercial shipyards as both may be equipped with quays, drydocks, extensive repair facilities, cranes, railways, etc. In addition, a number of different types of vessels may be present at commercial shipyards as well as naval bases, but the presence of warships, submarines, and service vessels will distinguish the base. Despite these similarities, naval bases will usually possess other characteristics of military installations such as housing, security fences and guard shacks, military equipment and recreational and training facilities. Naval stations located inland are usually engaged in basic military training or naval flight training. They tend, therefore, to resemble army

Figure 32: Ramps located in a marina.

Photo Interpretation Training Course

Transportation

Cultural Features 199

or air bases, unless the presence of ship-like structures indicate naval activity. Seaplane stations, which may be located on naval installations, are identified primarily by ramps, hangars and seaplanes in the water or onshore.

Vessels

During a war, the entire merchant marine of a belligerent nation may become a part of the armed forces of that nation. As such, each ship, regardless of its type, is of military interest. Thus, the photo interpreter is interested in every vessel capable of transporting men or supplies. Identification of vessels is of necessity, a specialty, but the general interpreter must still be familiar with the main types of merchant ships.

Passenger Ships

They are usually from 140 to 300 meters (450 to 1,000 feet) long and present a more streamlined appearance than other merchant ships. Fifty percent or more of their deck space is taken up by the central superstructure, and they have from 1 to 3 funnels (commonly known as smoke stacks).

Freighters

These vessels are the most numerous ocean-going merchant ships afloat. They are usually from 60 to 150 meters (200 to 500 feet) in length. They have blunt bows and sterns and parallel sides. Superstructure covers little area and may be split, but is usually in the relative middle of the ship. Freighters ordinarily have just one funnel that is located to the rear of the superstructure.

Tankers

Tankers used for transporting petroleum products are identified by a small bridge amidship, a single funnel near the stern, and a catwalk running the length of the ship. The bridge or superstructure is small in relation to the size of the entire tanker, which can be well over 300 meters (1000 feet) in length.

Warships

Warships are easily distinguished from merchant vessels by their shape. Major surface warships with the exception of aircraft carriers, have streamlined hulls when viewed on aerial photos. Cruisers and smaller warships have long streamlined hulls in relations to their width. In addition, naval vessels may also show a number of guns mounted in turrets or missile launching units on the center line of the ship and clustered around the superstructure. Aircraft carriers are easily identified by the large flat deck, aircraft on the deck, and deck markings. The carrier's superstructure is generally is mid-ship along the side.

Photo Interpretation Training Course

Figure 51: Helicopter carriers

Figure 52: Aircraft carriers

Figure 53: Examples of a cruiser and destroyers

Figure 54: A frigate and an air cushion vehicle

Figure 55: Fast patrol boats and a landing ship

Harbor Defenses

A variety of defense installations may be detected around a harbor and in a port area, not only for naval bases but also for commercial ports. Anti-aircraft guns and sea coast artillery may be present with land mines, beach obstacles, trenches, and casements, as part of local defenses. Underwater submarine nets and booms may be found at the harbor entrance to prevent entrance of unauthorized vessels and within the harbor to protect exposed points from torpedoes launched by aircraft, submarines, or torpedo boats.

Photo Interpretation Training Course

Figure 56: Submarines

Other Port And Harbor Features

Aids to Navigation (NAVAIDS)

The term *aid to navigation* means any device external to a vessel intended to be of assistance to a navigator. Assistance that is provided will aid in the determination of position, charting safe courses, or provide a warning to dangers or obstructions to navigation. This term includes lighthouses, beacons, sound signals, buoys, marine radiobeacons, racons, and the medium and long range radionavigation systems. The discussion of the aids to navigation in this section, however, will be limited to lights and buoys.

Lights

Lights on fixed structures can vary from the tallest lighthouses on the coast flashing with an intensity of millions of candlepower, to a simple battery-powered lantern on a wooden pile in a small creek. Located in fixed positions, which enable identification and accurate charting, lights provide navigators with a reliable means to determine their position in relations to the coastline and hidden dangers during daylight and darkness. The structures that house the light are often distinctively colored to facilitate their observations during daylight.

A major light is a light of high intensity and reliability exhibited from a fixed structure or on a marine site (except range lights). Major lights include primary seacoast lights and secondary lights. Primary seacoast lights are those major lights established for the purpose of making landfalls and coastwise passages from headland to headland. Secondary lights are those major lights, other than primary seacoast lights, established at harbor entrances and other locations where high intensity and reliability are required. Major lights are usually located at manned or monitored automated stations.

Figure 57: Light (secondary) at the end of a breakwater marking the entrance to the harbor.

Figure 58: A secondary light at the end of a breakwater.

Figure 59: A minor light powered by a battery, recharged through the use of a small solar panel.

A minor light is an automatic unmanned (unwatched) light on a fixed structure showing usually low to moderate intensity. Minor lights are established in harbors, along channels, rivers, and isolated locations.

Lighthouses

Lighthouses, all of which exhibit major lights, are placed where they will be of most use: on prominent headlands, at entrances, on isolated dangers, or at other points where it is necessary that mariners be warned or guided. Their principle purpose is to support a light

at a considerable height above the water. In many instances, sound signals, radiobeacon equipment, and operating personnel are housed in separate buildings located near the tower or building. Such a group of facilities is called a light station.

For many lighthouses the most obvious identifying feature is the tall, cylindrical tower with the light positioned at the top with a walkway around the glassed-in light. As previously mentioned, some may have distinctive large painted patterns on the tower that can also be used to identify this feature. Keep in mind that all lighthouses are not of this design, but the light on the top of the structure is usually discernible. Use of an ancillary source (i.e. Notice to Mariners) may be needed to locate some of these features.

Figure 60: Lighthouse with very distinctive markings

Range Lights

Range lights, or harbor beacons, usually consist of self-supporting, tapered lattice towers with lights on top and, in some cases, radar reflector panels on the sides. They are placed onshore in a manner as to sit in-line with the center of a deep-water channel or an entrance to a harbor. This line of sight may be visible on aerial photographs because of a clear cut

Figure 61: This is a graphic representation of the placement of range lights for this harbor.

from the rear light to the front beacon and down to the water. When these beacons are placed within a cultural area they may be lost within the clutter of features. The rear light is higher than the front light and at a considerable distance apart (this distance is variable depending upon the specific layout for the location). Thus, enabling the mariner to use the range by keeping the lights, structures, or radar returns in line during the progression up the channel. Range lights are sometimes used during daylight hours through the use of high intensity lights. Otherwise, the range light structures are equipped with day marks for ordinary daytime use.

Figure 62: Range lights

The lights discussed here are just a few of the many different types of lights used by vessels for navigation. Much more information is required about a light than just its location derived from the interpretation of aerial photographs. Therefore, refer to *Chart No. 1 United States of America Nautical Chart Symbols and Abbreviations*, prepared jointly by NOAA and DMAHTC; and DMA's *Pub. No. 9 American Practical Navigator, Bowditch*; or *Chart Specifications of the International Hydrographic Organization (IHO)* for discussions and symbology on the characteristics of lights and other hydrographic information found on charts.

Pipelines

General

In spite of the high initial setup costs, pipelines are still the most economical means of transporting liquid or gaseous materials, particularly when large quantities are involved. For this reason, pipelines are extensively used for the shipment of water, oil, gas, and other materials, as well as the movement of waste materials to disposal or treatment sites. Even solid materials, such as coal, can be pulverized and mixed with water to form a slurry, which can then be pumped

through a pipeline. Cities and industries could not exist in their present size and form without pipelines.

A pipeline exists to transport a large quantity of material from a producer to a customer, from a source to a destination. Movement along a pipeline is almost always in one direction only. If a return flow is needed, a second pipeline is utilized. This is different from the other transportation systems discussed, where movement in both directions is common. In this section, we will concentrate on pipelines used to carry materials between source and destination points. Pipelines internal to various facilities will be discussed under Chapter 4, Industrial Components.

Gases and liquids are fluids, that is they have no definite shape and conform to the shape of their container. They move or flow in response to gravity or other forces. Gases expand to fill the space they are contained in, and can be compressed into a smaller volume. Liquids are essentially incompressible, and will maintain a level, free surface if their volume is less than that of their container. It is these similarities and differences that dictate how gases and liquids must be handled. Liquids, because of their greater density and fixed volume, flow downhill readily, while gases need to be introduced into the pipeline under pressure in order to induce flow. For uphill grades, both fluids require pressurization. For short pipelines, such as those internal to a facility, the initial pressurization is sufficient to carry the material to its destination. For longer pipelines, a series of **relay stations** (**compressor stations** for gases and **pumping stations** for liquids) are required to overcome frictional losses and to move the material through uphill grades.

There are three types of pipelines, **feeder lines**, **trunk lines** and **distribution lines**. In any pipeline system, one, two or all three types may be present. Feeder lines are small diameter lines that collect the fluid from source areas, such as oil and gas fields, and transport it to a processing site, a storage site, a point of consumption, or to a trunk line. The trunk line is of larger diameter and transports the fluid to a processing or storage facility, a point of consumption, or to a system of distribution lines. The distribution lines are small diameter lines that divert part of the flow in the trunk line to a particular point of consumption.

Figure 1: Feeder pipelines in a small oil field. The oil is stored in the gathering tanks and sent through a gas/oil separator before being sent through the trunk line to the refinery.

Figure 47: Side haul and an end haul marine railway

Photo Interpretation Training Course

Chapter 3

210 Cultural Features

The appearance of the pipeline does not provide much of a clue as to the material being transported. The best clues to this information are the terminal and storage facilities, and relay stations associated with the pipeline. These facilities may be the only clues to the presence of a buried pipeline. The association of the pipeline with features such as oil fields, urban areas and reservoirs will also give an indication of the materials being transported.

Pipeline Routes

The location and appearance of a pipeline are determined by two main factors, the relative location of the source and destination, and the environmental conditions along the route. The relative locations of the source and destination dictate the type of terrain to be crossed. The environmental factors determine the specific route, whether the pipeline is placed under, on or above the ground's surface, and other special engineering adaptations.

Pipeline Route Location

The most important factor in determining the route of a pipeline is economy. First, the construction costs must be minimized. Therefore, whenever and wherever possible, the pipeline will follow level terrain and gentle slopes, and will be laid in straight lines. It will stay in open areas, rather than going through brush or forest, and will avoid hard to excavate soils if it is to be buried. The pipeline will go around rugged terrain and other adverse areas, if this does not significantly increase its length. There are no grade limitations on a pipeline. Increasing uphill gradients will increase the number of relay stations required along the route.

Second, it must be economical to use. This means moving the maximum amount of material through the pipeline with a minimum number of relay stations. These relay points are expensive to operate and are subject to breakdowns which would interrupt the flow of materials. Economy of use also means that it must be possible to tie in new feeder lines from new sources, or distribution lines to new customers. Where the pipeline is subject to deterioration, by electrolysis or other means, special adaptations must be made to protect the system from damage.

Finally, the pipeline must be economical to maintain. All points along the route of the pipeline must be readily accessible. For this reason, pipelines are often placed along the right-of-way of other transportation systems, such as roads, railroads and powerlines. This also allows the pipeline to use existing bridges to cross over rivers and other obstacles. The route must be kept clear of any vegetation other than grass. The resulting cleared way can be readily observed on imagery of even medium to small scales. Hazards to the pipeline, such as freezing, flooding, erosion, deterioration, earthquakes, vandalism, etc., must also be taken into consideration.

Photo Interpretation Training Course

Figure 2: Tank types and the petroleum products associated with them

Pipeline Placement

The most inexpensive method of laying a pipeline is to set it on the surface of the ground. This minimizes excavation to that extent required to provide an even surface to support the pipeline. In most cases, the pipeline does not actually sit on the ground, but is supported by a series of small piers which compensate for irregularities in the ground's surface. As well as minimizing construction costs, this also leaves the entire length of the pipeline readily accessible for maintenance. Setting the pipeline on the ground's surface leaves it exposed to the weather, and to accidental damage or vandalism. It also becomes an obstacle to any vehicles traversing the area, and special accommodations must be made where the pipeline crosses a road or railroad. Therefore, pipelines are normally set on the surface only in sparsely populated areas with warm climates, or for expedient and temporary pipelines, such as collection feeder pipelines in oil fields, and those associated with military operations. Pipelines are also set on the

Figure 3: Two types of pipeline crossing points

surface in areas with little soil cover or hard to excavate soils.

Crossing points must be constructed where surface pipelines cross roads or railroads. At one type of crossing point, the pipeline is simply buried underground for a short distance, allowing the road or railroad to pass over it. These are easily recognized, as the pipeline disappears at the crossing point, and there is no discernible change in the road. An other alternative is to elevate the pipe a sufficient distance to allow traffic to pass under it. This is accomplished by placing a vertical jog or loop in the pipeline. The shadow of the elevated section of pipeline is very distinctive. A third method is to build a ramp over the pipeline. This is used extensively in oil fields where feeder lines are placed on the ground's surface. The ramp is usually easy to spot, as the pipeline is covered for only the width of the ramp. The shadow of the ramp may be visible. Frequently, several tracks or loose surface roads will converge at the crossing point.

In some cases the pipeline must be elevated above the ground's surface. The

Alaskan pipeline, for example, is set above the ground in order to prevent heat from the warm oil in the pipeline from melting the permanently frozen ground. Pipelines may also be elevated for short distances when crossing areas subject to flooding, or in areas of electrolytic soils, where contact with the ground would cause rapid deterioration of the pipe.

Many pipelines, particularly in the more industrialized countries, are buried underground. This protects them from damage and the weather. Placing the pipelines underground avoids interfering with other uses of the surface. This also makes detecting and identifying pipelines on imagery much more difficult.

Figure 4: function manifold with valves where a distribution line exits the trunk line.

Although most of the pipeline is buried, some parts must remain exposed for operational and maintenance purposes. These, along with the cleared way, can be used to locate and identify both buried and above-ground pipelines.

Components

A **manifold** is a connection point, where two or more pipelines meet, or where a valve, regulator, meter or other control device has been installed. **Valves** are used to control the flow of fluids through a pipeline, and to shut down the pipeline in case of a leak or break. **Regulators** reduce the pressure of the gas as it enters distribution lines. Valves and regulators are frequently controlled by microwave radio, so that emergencies can be controlled immediately, rather than waiting for a crew to reach a remote location.

Relay stations, storage facilities and terminals are also located on the surface. In addition, pipeline route markers are placed at intervals along the pipeline, especially where the pipeline crosses a road or railroad. These markers serve as a warning to anyone who is excavating in the area that their activity may damage the pipeline.

Figure 5: Large pipeline manifold at an oil pumping station

Steel and cast iron are the dominant materials used for oil and gas pipelines. Concrete is often used for larger water systems and some sewer systems. Masonry and tile pipes have been used, particularly in older systems. Bamboo and flexible hose have been used locally for small systems, and plastic piping is becoming more common. The smaller, lightweight, "primitive" pipelines may look much more irregular than their larger counterparts.

Identification of Pipelines on Imagery

Surface pipelines will appear narrower than roads or railroads, and will have regularly spaced angular jogs (**expansion loops**) that compensate for expansion and contraction of the pipeline due to temperature changes. Expansion loops are found on all pipelines, but they are much more closely spaced on steam pipelines. The closely spaced expansion loops are the key to identifying steam pipelines.

Above ground pipelines are distinct from and darker than the surrounding ground. Buried pipelines may be revealed by the scar in the earth, and their trace may be discontinuous.

Pipelines are straight, with angular bends, but may be very gently curved. Junctions and branchings are rare (except around oil and gas fields and urban distribution systems), and are normally angular, but may be tangential. Although the alignment is straight, there will be little evidence of cuts and fills, as pipelines follow the surface of the ground. A cleared way will be present whenever the pipeline passes through a forested area. Pipelines are more likely to cross the drainage pattern than to follow it.

Figure 6: An expansion loop on an above ground pipeline. Note the small pedestals upon which the pipeline rests.

When a pipeline crosses a body of water, it is normally placed on the bottom, in which case there will be no visible indicators of its presence. A surface pipeline will be observed entering the water. A buried pipeline may have route markers placed along the shoreline at the point of entry. Occasionally, the pipeline may be suspended from floats, and remain on the surface. The contrast between the water and the pipeline and its floats will make it easy to locate and identify. The floats can be as elaborate as a set of small barges or pontoons, or as simple as a series of empty 55 gallon barrels. Floating pipelines would only be used in areas where they would not interfere with maritime traffic.

Relay Stations

As a fluid passes through a pipeline, friction slows down its movement. Uphill grades along the route require the fluids to be boosted up the grade. For this purpose, relay stations are placed at intervals along the pipeline route. Relay

Figure 7: Diagram of an oil pumping station

stations consist of pumping stations (for liquids) or compressor stations (for gases) along with pipe manifolds, regulating tanks, storage tanks, and other associated features. Relay stations propel the fluid through and regulate flow in the pipeline. The spacing of the relay stations depends mainly on the topography, but is also influenced by the size of the pipe, the speed of movement and the type of material being moved. Over similar terrain, pumping stations will be more

closely spaced (16 to 100 km) than gas compressor stations (80 to 160 km).

Both pumping and compressor stations have a small, narrow, rectangular building which houses the pumps or compressors. It may have a gabled or flat roof, but will always have ventilators spaced along the length of the roof. If the pumps are powered by internal combustion engines, the exhaust pipes, with mufflers, will be visible along one side of the building. The number of pumps or compressors, and thus the length of the building, are proportional to the size and capacity of the pipeline.

An oil pumping station will usually have two or three small, regulatory tanks with cylindrical, flat or peaked roofs nearby, as well as a pipe manifold. A gas compressor station will usually have a pipe manifold, and a gasometer may or

Figure 8: Diagram of a gas compressor station. Note the presence of the cooling tower and blimp tanks.

Figure 9: A typical gas compressor station. Blimp tanks are located at the far left of the picture. Individual coolers for the compressors are on the right side of the building. Note the shadow of a water tower in the foreground.

may not be present. Water pumping stations consist of a small building housing the pumps and an elevated or tower-mounted regulatory tank. Sewage pumping stations are small, plain buildings with no associated tanks. The sewer line will not be visible. Within an urban environment, the small sewage pumping station will be hard to detect.

A "city gate" is a station on a natural gas pipeline, located near a major point of consumption (such as a city) where the pressure is reduced and the flow is metered. The gas then flows along a branch line to the point(s) of consumption. The station consists of a manifold with valves, meters and regulators. A small building may be associated with the manifold.

Figure 10: A pumphouse typical of those associated with water wells. Sewage pumping stations are similar in appearance.

Terminals

The large size and distinctive appearance of terminal facilities make them easy to identify. The storage facilities associated with the terminal are the best indicators of the contents of a pipeline, as each product has distinctive storage requirements. Since a pipeline is normally used for one-way transportation, there will be a source terminal and a destination terminal. Occasionally, a pipeline will end at a point of consumption, such as a manufacturing plant, where the obvious clues are absent. In these cases, a detailed examination of the components of the facility must be examined.

Source terminals can be oil or gas fields, reservoirs, rivers, storage areas, processing plants, or transshipment facilities. In any case, there will be a terminal pumping or compression station to propel the fluid through the pipeline. Terminal pumping stations are large buildings, substantially larger than relay stations. Destination terminals can be storage areas, processing plants, transshipment facilities or points of consumption. Storage facilities will also be present.

Figure 11: POI bunkering pier. Note the relatively narrow pier, the presence of pipelines and tanks, and the absence of cranes and other cargo handling equipment.

Figure 12: An oil tanker moored at a loading buoy. Note the relatively large size of the buoy and the pipeline emerging from the left side.

Figure 13: A closeup of the loading buoy from figure 12

An oil terminal pumping station will have a large pipe manifold, and a complex of pipes around the building. Storage facilities consist of cylindrical tanks, and occasionally spherical or spheroidal tanks. Open oil reservoirs are found at some oil fields.

A gas terminal pumping station will also have a large pipe manifold, but not as much pipe around the building. The building is high-roofed, and smokestacks are present. Storage facilities consist of wet or dry gasometers, but cylindrical, flat-roofed tanks may also be present.

Water purification plants are located near the urban areas which they support. Associated with the purification plant is a pumping station which sends the water to the elevated tanks and water towers that supply the area. The building is large, frequently more than 50 meters (150 ft) in length. If a pipe manifold is visible, it will be simple, with large diameter pipe. Several small tanks for chemicals

Figure 14: A large gas terminal pumping station. In this case, the compressors are placed in the open rather than inside a pump house.

at other points where it is necessary that mariners be warned or guided. Their principle purpose is to support a light

Photo Interpretation Training Course

Chapter 3

220 Cultural Features

used in water purification will be present. The water source (reservoir, river, wells, etc.) may be nearby, or the water may be brought in from a distant source via pipeline or aqueduct.

Sewage treatment plants are characterized by the presence of a number of round and rectangular aeration, sedimentation and treatment ponds. Sewage treatment plants are larger than water purification plants, and have more ponds. There will not be a water tower present.

For more information about sewage treatment plants, see Disposal Industries in Chapter 4. Oil and gas processing plants, and water treatment plants are discussed in Chapter 4, Processing Industries in the same chapter.

Aqueducts

An aqueduct is an artificial channel designed to transport water, for domestic purposes, from a remote source. The aqueduct is constructed with a steady downhill gradient, and the water flows to its destination without the aid of pumps. They are different from pipelines, in that the water is not confined to a closed conduit, and that water flow is maintained by gravity rather than pumping. Aqueducts are used worldwide, and extend from the water source to a city or town, or to industrial plants, sometimes emptying into another reservoir or a water filtration plant.

Aqueducts are normally built by excavating a trench in the ground's surface. Where soil conditions permit, the earthen slopes form the sides of the aqueduct. In many cases, the aqueduct is lined with masonry, concrete or asphalt to prevent erosion and loss of water.

In order to maintain the steady downhill gradient, aqueducts must be carried across valleys and other depressions on man-made, bridge-like structures. Various construction types are possible, but most common is the Roman masonry arch. Taller structures commonly use a multi-level arch. The aqueduct can be carried over smaller streams on flumes, or under the stream via pressure pipes known as inverted siphons. In some areas, it may be necessary to carry the aqueduct through tunnels cut into the hills.

Note: the term aqueduct is sometimes applied to the bridge-like structure, rather than the channel. This is especially common when referring to the Roman aqueduct bridges mentioned above.

Photo Interpretation Training Course

Transportation

Cultural Features **221**

Figure 17: An aqueduct crossing over a river

Aqueducts are usually open, but may be covered to reduce water loss through evaporation. Where an aqueduct crosses a valley on a bridge, it may also be covered, allowing a road to use the same structure.

The majority of aqueducts have sharp, straight or gently curved, man-made banks. They appear similar to canals, but are generally much smaller. Most aqueducts are between five and twenty meters wide and extend from less than a half kilometer to many kilometers in length. The water in the aqueduct will be dark, contrasting with the lighter tones of the aqueduct itself (white to light gray in tone for concrete, medium gray for metal or masonry, and dark gray to black for asphalt). Depending on the viewing angle, reflections from the water may be visible. Covered or dry aqueducts will have a lighter color, depending on the construction material. The shadow from a dry aqueduct would fall inside the channel, while the shadow of a covered aqueduct, if any, will fall outside.

Larger aqueducts may be confused with canals. There will be no boats present on an aqueduct, and thus the clearance under bridges crossing the aqueduct, and the vertical clearance in tunnels can be very low. In addition, there will be no locks, or other facilities common to canals. Inverted siphons are only used on aqueducts, and will not be found on canals.

The dark color of the water, and the regular sides and even width of the aqueduct, may make the feature resemble an asphalt road. Ripples or reflections would indicate the presence of water, and the absence of a centerline, or vehicular traffic suggest that it is not a road. Intersections with other aqueducts are rare, and aqueducts will pass over or under other features. Roads would have frequent intersections. Dry or covered aqueducts may look like concrete or masonry surfaced roads. Again, the lack of vehicles or centerlines, and the nature of the intersections, can be used to show it is not a road.

Photo Interpretation Training Course

Qanat (Karez)

A Qanat (or Karez) is an artificial underground conduit, that collects ground water and carries it to a location where it can be used for drinking or irrigation. It is characterized by a linear array of holes, which are surrounded by a mound of soil excavated from the holes. The holes are dug at regular intervals and connected underground to form a continuous conduit. The gradient in the conduit is steadily downhill and water flows by force of gravity. These features are found in arid areas, where surface water is rare, and the level of technology is low. The term qanat is used in the Middle East and northern Africa, but in western China it is called a karez.

Qanats are also found in Spain, Syria, Iraq and Pakistan, but are most extensive in Iran. Invented by the Persians in 3000 BC, there are currently over 22,000 qanats, comprising 270,000 km (167,770 mi) of underground conduits, that supply about 75% of Iran's irrigation water.

The qanat will begin in an alluvial fan, an ephemeral lake, or another area where the water table is near the surface. Several qanats can be used to bring water to a central location. The evenly spaced series of holes with the adjacent debris mounds make this an easily recognizable feature. The shadows within the holes stand out against the generally light tones of the arid landscape.

A qanat may be abandoned if the water table drops, the water becomes saline, or if a more dependable supply of water is found. Then the lack of maintenance will result in erosion and collapse of the holes and possibly vegetative growth in and around the holes.

Figure 18: A set of four qanats bringing water to a small reservoir from which it is distributed via a series of irrigation ditches.

CHAPTER 4 – INDUSTRIES

Introduction

Chapter four deals with all aspects of industries. This includes components and industrial equipment, the extraction and transportation of raw materials, waste disposal, power generation, processing, and fabrication from materials provided by processing industries.

The text will cover the basic processes used in each industry, photo-identification of the industry, and a special emphasis on specialized equipment associated with that industry.

Industrial Components

There are pieces of equipment common to most industries. This common specialized equipment includes components used in handling, conveying, storing, and processing the materials for industry. The materials can be in solid loose or piece good forms, as volatile or non-volatile gases, and liquids. Every industry has the common problem of delivering raw materials and shipping finished products; transferring materials from storage, between processing sections, and onto transportation; and holding materials during processing.

This equipment is identified through its shape and size. The presence of some equipment is an indication of the process occurring in the plant. No one particular piece of equipment is definitive of a process but it does indicate industrial processing. Industrial components fall into one of five categories. These are storage, material handling, transportation elements, processing equipment, and support equipment.

Storage

Material storage is probably the easiest component to identify and one of the most prominent features of an industry. Depending on the material to be stored, storage can be required for solids, liquids, or gases. The type of solid, i.e., granular, piece goods, or bulk items mandate a certain kind of storage. The volatility of the liquid or gas also mandates a certain treatment.

Open Storage

Some materials are not sensitive to changes in temperature and humidity. These materials can be stored wholly in the open or in the open with minimal cover. Raw materials such as ores are typically stored in large open piles near transshipment and processing areas.

Figure 1: Stockpile

Extremely large stockpiles of ore are common at extraction and processing plants. Essentially this storage is a pile of material of varying tint (depending upon the material). Other materials that may be stored temporarily in the open, especially in semi-arid climates, include grains and vegetative products.

Often end products from an industry will be stored in the open. Examples of some of these materials include building materials, steel products, and wood.

The configuration of the stockpile sometimes defines the stored product. These stockpiles mostly represent finished products and are found near the outbound shipping area.

Figure 2: Open Storage Materials Key

Figure 3: Open Storage Depot

Enclosed Storage

Most material used in industrial applications is sensitive to changes in humidity and temperature. Some material is photo-sensitive. These materials must be stored in enclosed areas for protection. Additionally, the very nature of some materials makes open storage impractical. Liquids and gases are obviously materials requiring closed storage. Of course some liquids can be stored in open reservoirs if volatility and contamination are not a concern. Other granular materials can be dispersed by winds and water and require closed storage. The dangerous nature of explosives and highly volatile fuels requires additional protection by either burying the storage area or through the addition of earthen walls and berms.

Warehouses

A common storage medium is the warehouse. Warehouses are commonly used to store bulk items, crates, and boxes. Sometimes granular material such as fertilizer (at fertilizer plants), sand and salt mixtures (at highway maintenance garages), and grains (at industrial sugar plants and grain elevators) will be stored in warehouses. The loose bulk material is stored in large domed storage structures or in large A-frame warehouse buildings. The typical construction material is sheet metal for the A-frame and concrete or steel framing for the dome storage.

However, most warehouses are single story flat or gable roofed structures that are very long in relation to their width. The warehouse is notable because of the lack of windows and lack of the numerous roof vents or cooling facilities normally associated with manufacturing and processing areas. The warehouses are usually aligned in an orderly arrangement. When associated with manufacturing and processing plants, the warehouse area is located adjacent to the outgoing freight or incoming raw material transshipment points. In all cases, the warehouse will have access to a transportation

Figure 4: Warehouses at Freight Terminal

Figure 5: A-Frame Warehouse

network. Sometimes the warehouses will be connected by a road network. Steam pipelines may convey heat for temperature control. Generally, the warehouse area is distinct from an open storage area.

Another type of warehouse is the bunker (referring to a low solidly constructed structure), either above ground, buried, or partially buried. These structures store

Figure 6: Earth Covered Explosive Storage Bunkers

hazardous and explosive materials. As with normal warehouses, the bunkers are aligned in neat orderly rectangular rows. These storage areas are most likely to be fenced with guard houses as access control points. Bunkers are readily identified by the orderly arrangement of earth covered mounds, casting distinctive shadows. Additionally the bunkers will be linked by road or rail lines.

Mobile material handling equipment may be visible in the area. The material handling equipment usually consists of forklifts or other specialized lifting and transporting equipment. Often the sides or ends of the warehouse will have freight docks to accommodate trucks or rail cars. Warehouse areas associated with rail, road, and shipping points are usually fairly clean, utilitarian, and neat facilities without the general clutter found around processing and manufacturing plants. Warehouse areas found in conjunction with large metropolitan areas will be found around the outskirts of the city or near manufacturing and processing zones.

Industries

Cultural Features 227

Figure 7: Open Storage Bins (Bunkers)

Figure 8: Silos

Silos, Bins, Bunkers, and Hoppers

Most solid chemicals and other granular materials require a method to both hold in storage and dispense for use. These storage mediums have in common their design to retain a solid granular material and dispense that material from the bottom. The material dispenses with the aid of a conical or pyramidal funnel. In the case of most silos, bins, and bunkers that funnel is internal and not visible. In the case of hoppers, the funnel is visible from outside the structure. These storage containers are filled from the top by way of conveyors (belt, screw, or bucket). Another method of fill involves driving the transporting vehicle over the container and releasing the contents directly into the container. Silos, bins, bunkers, and hoppers can occur singly, in groups, or inter-connected series.

Figure 9: Inter-connected Silos

Figure 10: Silo and Grain Bin (Bunker)

A word about terminology is necessary. Silos, hoppers, and bunkers are types of bins. A silo is a deep bin while a bunker is a shallow bin. In the U.S., if $H > 1.5(A)^{1/2}$ [or in Soviet Code if $H > 1.5D$ (circular bins) $H > 1.5a$ (rectangular bins)], the structure is

Figure 11: Bins and Silos with Visible Hoppers

Photo Interpretation Training Course

Figure 12: Hopper Discharge Type

a silo (H = height of container excluding hopper, D = diameter, A = area of the bottom of the container, and a = length of the longer side). Otherwise the structure is a bunker. The characteristics of the stored material (density, coefficient of friction, and angle of repose) determine whether a shallow or a deep bin is used. Most bins are equipped with hoppers to remove the stored materials.

In general use, what is often referred to as a hopper is a bin with a visible hopper. Bins can be rectangular,

hexagonal, or circular in cross-section although the circular bin is by far the most common. Most large industrial bins are made of concrete, a few are made of metal. Smaller bins tend to be made of concrete, metal, wood, and more and more, of composite materials. In agricultural use, grain bins are usually bunkers made of metal over a wood frame with conical sheet metal roofs. Some newer grain bins are of composite materials. Silos in agricultural areas are commonly used for storage of both silage and grain products. Silos in agricultural areas used for silage are made of masonry or concrete to withstand the high

Figure 14b: Agricultural Silos
Right to left: Masonry, Metal, Composite
Photo Courtesy G. J. Busbur

temperatures generated during the fermentation of the silage. Silos used for grain storage can be of concrete, metal, or composite materials. Most grain elevators are made of inter-connected concrete silos.

An additional note on objects that look like bins but aren't. In some geographic areas, particularly China, grain and grass products are stored in an upright position within an enclosure of scrap wood or fencing materials. The vegetative matter is further protected by the addition of a roof or cap of grasses. This looks like a grain bin but actually is not a permanent structure. Of course, this construct will not exhibit a radar reflectivity. Certain huts or dwellings commonly found in Africa, Asia, and South America also resemble grain bins but are in reality houses. Some configurations of water towers can also resemble silos. An important item to remember when identifying bins is the associations of features. Agricultural bins will be in farming areas, industrial silos will be found in manufacturing and processing plants, and water towers will be found in conjunction with water treatment plants, industries, and associated with inhabited urban or rural areas.

Tanks

Tanks are used to store fluid materials (gases or liquids). A storage tank is designed to store the fluid at a particular pressure. This could be atmospheric pressure or several hundred psi. The design accommodates a particular type of material, i.e., caustic or flammable. When the material is dangerous due to an explosive or inflammable nature, the tanks are bermed. This protects personnel and property in case of leaks or ruptures. In some cases, to provide additional security, the tank may be buried.

Almost every manufacturing and processing plant uses tanks. The tank is ubiquitous to industry. Often the tanks are found arranged in orderly rows, contained within a berm.

Tanks are classified by size and shape. In fact, the tank's configuration (size, shape, and number) in most cases can be used to enable the identification of what is stored in the tank and its use. This is especially true if even a partial identification of the utilizing industry can be made.

Figure 15: Upright Cylindrical (CAN) Tanks

Figure 16: Shadows for Cylindrical Tanks

kerosene, alcohols, and crude oils. Domed tanks are used mainly in the storage of volatile fuels and chemicals. The dome flexes with pressure increases in the liquid due to evaporation. However, this type of tank is not designed to withstand pressure build-ups. Tanks designed for atmospheric pressure storage typically have a system of roof-top vents or pressure relief valves.

Cylindrical tanks are commonly placed on top of metal frameworks to serve as water supply towers. Water towers are easily identified due to their association with water treatment plants and domestic water users.

Tanks containing non-flammable chemicals usually are not bermed. Also, chemical storage tanks are normally connected across the top by walkways and a system of small (<4") piping.

Vapor Dome

The vapor dome tank is a cylindrical structure with a flat or domed roof. Additionally, the tank has a large dome on top of the tank roof. The dome allows for the collected vapor to accumulate and condense to fall back into the tank. This large tank is used in the storage of volatile fuels such as gasoline. These tanks are rare and will usually be found at distribution centers for fuels. The tank will normally be bermed.

Upright Cylindrical Tanks

Upright cylindrical (or can) tanks are used in storage of a variety of liquid materials. This type of tank can have a flat, peaked, or domed roof. The roof is fixed to the top of the tank.

The flat roof tank is used in the storage of crude petroleum, fuel oil, vegetable oil, tars and asphalt, molasses and sugars, chemicals, and water. Peaked roof tanks are used in the storage of volatile fuels such as gasoline and

Figure 17: Peaked Roof Gasoline Storage

Photo Interpretation Training Course

Industries

Cultural Features 231

Floating Top Tank

The floating top or pontoon top tank is used for the storage of volatile liquids and gasolines. The roof is not fixed but floats on top of the liquid. These large tanks are commonly found in bermed groups in fuel distribution centers and tank farms. The floating top minimizes the accumulation of vapors.

Figure 20: Pontoon Tank

Gasometers

Gasholders or gasometers are used solely for the storage of gases. There are two types of gasometers, the dry gasometer and the wet gasometer. The dry gasometer is a tall upright cylindrical tank with a dome on the top. The dry gasometer stores natural gas, industrial gas, and a variety of other gases. The wet gasometer is a telescoping tank contained within a steel framework. This steel lattice framework makes identification easy (especially when the shadow is fully visible). The lower section of the tank contains water to form a seal. As gas enters the gasholder, the pressure pushes the sections up, maintaining a constant pressure. The wet gasometer is used in the storage of natural gas, industrial gas, hydrogen, nitrogen, and oxygen.

Both types of gasometers are usually very large tanks. These are the largest of the tanks. Tank height can exceed 76 m (250 ft). Gasometers are found associated with coke, iron, and steel plants. They will also be found associated with natural gas distribution in urban areas.

Figure 21: Shadow

Figure 22: Gasholders

Figure 24: Wet Gasometer Operation

Figure 23: Wet Gasometer Shadow

Photo Interpretation Training Course

Bullet

Bullet tanks are elongated cylinders with rounded ends set upright. These tanks are used for the storage of high pressure gases or liquefied gases (such as LPG). These tanks are rarely found alone, but will be grouped in closely spaced rows. These are small tanks.

Figure 25: Bullet Tank

Figure 26: Bullet Tank Shadow

Blimp

Figure 27: Blimp Tank

Blimp tanks are elongated cylinders with rounded ends set horizontally. Blimp tanks are usually placed on a framework of concrete or steel. The legs may protrude from under the tank and be visible. These tanks are used for the storage of high pressure gases or liquefied gases (such as LPG). These tanks may be found grouped in closely spaced rows. They may also be found singly. These may be small tanks or size may range to medium. These are the type of tank used in "LPG" distribution (propane, and butane).

Figure 28: Blimp Shadow

Figure 29: Propane Storage in Blimp Tank
Photo Courtesy G. J. Busbur

Horizontal Cylinder

The horizontal cylindrical tank with flat ends is commonly used for the storage of fuels. These tanks are found in use by retail establishments and the user to store small and moderate amounts of fuel. This is the typical tank buried at gas stations and found throughout the country on farms, mounted on small metal frameworks.

Figure 30: Horizontal Gasoline Storage Tank
Photo Courtesy G. J. Busbur

Spherical

These storage tanks can be a pure sphere, a flattened spheroidal shape, or a noded spheroidal shape. The spherical (Horton sphere) tank is used in the low pressure (15-55 psi) storage of LPG, natural gas, and industrial gases; or helium, nitrogen, and oxygen gases. Spheroidal tanks store highly volatile liquids such as LPG. The noded tank is found associated with gasoline storage and the storage of other highly volatile fuels.

Figure 31: Spherical Tanks

Figure 32: Spherical Nitrogen Storage Tank
Photo Courtesy G. J. Busbur

A special note on the tonal appearance of tanks. Sometimes a mixed tonal pattern of light and dark tanks is found. The dark tones may be the result of stains or rust on the tank. Dark toned tanks result from a dark toned paint. Dark toned paint helps to heat the tank (solar radiation). The heated tank aids in reducing the viscosity of the heavy fuel or heavy oils contained within the structure.

Light toned tanks, in these cases, hold light fuel oils or volatile fuels which do not require the increased temperature in order to flow. The mixed tonal pattern is often found in at POL storage and an oil refinery.

Assemblages of solid black tanks are often used to store viscous materials such as molasses. Extremely light, bordering almost brilliant white, tanks could be insulated tanks for storage of LPG and LNG.

Figure 33: Spherical Tank Shadows

Materials Handling

This section on material handling addresses the methods of moving solids around the industry. The raw materials, semi-finished, and finished products must be moved numerous times during processing and fabrication. Numerous specialized devices have been created to accomplish this goal. Most of the specialized handling gear falls into one of three categories. These are cranes, mobile handling equipment, and conveyors. Pipelines, used to carry liquids and gases will be handled in a separate section.

Cranes

Cranes are used extensively in fabrication industries. To some extent some types of cranes are used in processing plants. A modern plant has a considerable array of lifting and materials handling equipment to move the heavy materials. The lifting equipment is composed of derricks and cranes. Identification of the type and capacity of the lifting equipment aids in assessing the capabilities of the plant. Cranes are grouped by their identification elements into cantilever, jib, gantry, bridge, derrick and shearlegs, cable, and pontoon (floating) cranes. The lifting apparatus on the crane can consist of a hook, a grab bucket, or specialized container attachments. The purpose of a crane is to lift and move the load from one spot to another.

Cantilever Cranes

Cantilever cranes are composed of a horizontal counter-balanced beam mounted on top of a tower. The load can be lifted and positioned laterally along the length of the beam. The crane arms rotate on the pedestal. Three types of cantilever cranes are tower hammerhead, elevated, and giant hammerhead. The tower hammerhead and elevated cantilever cranes move along on tracks while the giant hammerhead operates from a fixed base.

The tower cantilever crane is a beam crane with rails at the base. The elevated cantilever travels on a set of elevated rails or runways. Tower hammerhead and elevated cantilever cranes are used for construction and repair. Their capacity runs from 5—20 tons or more. A specialized tower crane is the tower transporter. This crane is used to load and unload bulk material such as grains and ores. The bucket picks up the load, runs it under the tower, and unloads on the opposite side. Most cranes of this type are found in port facilities and ore processing plants.

Figure 34: Crane Components

Figure 35: Tower Transporter

Giant hammerhead cantilever cranes are towering massive cranes with a fixed base. These cranes are used in lifting massive objects such as boilers and large sub-assemblies. General capacity is 100 – 300 tons or better.

Figure 36: Cantilever Crane Types

Jib Cranes

Jib cranes are characterized by inclined booms (called jibs). The load is positioned laterally by raising or lowering the jib. The maximum reach for the jib crane depends on jib length, load weight, and jib angle. Types of jib cranes include tower jib, elevated jib, portal jib, semi-portal, locomotive jib, automotive jib, and the fixed-base jib.

The tower jib is mounted on a tower with rails at the base for travel. The crane is used for construction along the building ways. The capacity runs from 5 – 30 tons or more.

The elevated jib is mounted on elevated rails for movement. This crane is also used for construction in the building ways and has a capacity of 2 – 30 tons or more.

The portal jib is a crane is a boom crane mounted on a portal type base (large movable base with four legs and high clearance). The crane is used for heavy construction and repair with a capacity of 5 – 25 tons or better. The semi-portal crane has one side of the portal attached to a structure such as a building.

A locomotive jib is a jib crane mounted on rails with a low cab. The crane is used for repair and movement of materials within the industrial plant. The capacity runs from 1 – 20 tons and upward. Automotive jib cranes are boom cranes mounted on wheeled or tracked bases. This is the common crane found in almost any construction project. This crane is used for general utility purposes and has a capacity of 1 – 5 tons or so.

The fixed-base jib is a boom crane mounted on a fixed-base. The crane is usually used in shipyards and has a capacity of 5 – 10 tons or more.

Figure 37: Jib Crane Types

Gantry Cranes

The gantry type crane is an elevated horizontal bridge mounted on one or two uprights that travel on rails. Or the gantry can be a bridge traveling on elevated runways. Types of gantry cranes are gantry, semi-gantry, bridge, and multiple-bridge. The load is hoisted by hook or buckets to the required height and moved laterally along the bridge. The entire bridge section can be positioned along the length of the supporting track.

Figure 38: Gantry Crane Types

A gantry crane is an elevated bridge supported at either end by uprights that run on rails at the base. This crane is usually found over assembly and storage areas. The crane moves material for construction and storage. Capacity is 20 – 50 tons or more.

The semi-gantry crane is a horizontal bridge supported by one upright. The other end is supported on rails attached to the wall of a building. The capacity is a minimum of 5 – 50 tons. The crane provides for movement of material anywhere within the industry and is attached to the building.

Bridge gantry cranes are elevated gantry cranes traveling on trestle or otherwise elevated rails. The cranes are found over buildings, assembly, and storage areas. This crane has a minimum capacity of 5 – 150 tons.

Figure 39: Transporter Crane

Multiple bridge gantry cranes consist of two or more elevated bridges traveling on the same rail and same set of bridges. These cranes are used in construction and storage areas within the plant. The capacity ranges from 5 – 25 tons or more. These cranes are found in areas where the size range of the materials is great.

Figure 40: Bridge (Transporter) Cranes

Another type of gantry is the bridge crane, also called the bridge transporter. This crane operates in a manner similar to the tower transporter. It is also used in loading and unloading bulk grain and ores.

Derrick and Shearlegs Cranes

The construction of derrick and shearlegs is different as is their range of movement. However both play minor roles in shipbuilding and construction projects. A derrick is an arrangement of masts, guys, and braces usually consisting of a

Figure 41: Derrick and Shearleg Cranes

vertical mast with an inclined boom. Derricks are fairly small with a capacity of 1 – 10 tons. These cranes are used in fitting-out and repair work where the load is small and great mobility of the load is not required. They will be found in dry-docks, along wharves, and positioned on vehicles to provide integral loading and off-loading capabilities.

Shearlegs are A-frame structures secured by beams and braces directly to the ground. They are commonly found at graving docks or wharf structures (quay, wharf, or pier). They are used in fitting-out and repair work where only hoisting is required since these cranes cannot swing a load. The capacity runs around 1 – 30 tons.

Specialized Cranes

There are several highly specialized devices that can be classified as cranes. Most of these are found in ports and are used in loading and loading vessels. Container cranes are a type of tower crane designed to load export containers (conex). A coaling tower or coaling hoist consists of either a car hoist or a bucket system designed to handle loose solids. Another type uses a continuous bucket system (conflow) to unload loose solids from ships. Typically this system is also suspended from a tower.

Cable cranes (sometimes called aerial cableways, refer to the subject of conveyors) are rare and consist of a set of cables supported by two or more large trestles. Usually they are found spanning assembly areas with a hoisting trolley moving along the cable. Their capacity is fairly small, from 2 – 5 tons.

Figure 42: Container Crane

Figure 43: Conflow (Continuous Flow)

Figure 44: Coaling Tower

Floating Cranes (Pontoon Cranes)

Floating cranes are used intensively in shipyards and repair facilities to augment other cranes. These cranes are constructed on barges to allow free movement within the port area. Most floating cranes are floating jib cranes or floating shear-leg cranes. They are used for fitting-out and repair work. The capacity can run from 5 – 150 tons. Some floating cranes are specifically designed to handle extremely large loads. These are commonly found in shipyards and construction facilities building oil-field rigs for offshore. The capacity runs into hundreds of tons of lift.

Figure 45: Floating (Pontoon) Cranes

Mobile Equipment

Since most cranes are limited to a specific range of operations, other pieces of equipment are used to manipulate materials out of range of the cranes.

Forklifts provide a medium to transfer large crates and other solid objects around the fabrication industry. Other vehicles may include front end loaders, bulldozers, wheeled dozers, power shovels, and tractor-trailers. Draglines and dredges are found associated with extraction industries (mining) and are covered within that section.

Figure 46: Powershovel

Conveyors

A central necessity in fabrication plants is the ability to move materials through raw storage yards, through the production process, and out to the shipping department. The most efficient method of handling materials within most plants is the conveyor. The term conveyor refers to a driverless and wheelless vertical or horizontal transportation system. Conventional elevators, hoists, and cranes are excluded from this classification.

Figure 47: Belt Conveyor System

There are many types of conveyors. Each is designed to handle a certain class of material, i.e., loose solids, bulk solids, crates and piece goods, or granular solids. Some of the general classes or conveyor types include screw (augers), flight and apron (metal pans mounted on endless chains or transverse scrapers in troughs), bucket (vertical bucket elevators and chains), rollers, pneumatic and hydraulic (dust catchers and flumes), overhead (tram and overhead rail), and belt. Conveyors can be powered by gravity, electricity, or pneumatics.

Many of the conveyor systems operate within the plant buildings. Others operate transferring materials from outside storage. Some systems transport material for miles. Most of the visible conveyor systems consist of the bucket, screw, and apron or flight conveyors used to load silos and bunkers. The most common visible system is the belt conveyor. These also tend to be the longer systems along with overhead trams used in aerial cableway systems.

No matter which system is used, the material must initially be placed on the conveyor. In the case of granular solids stored in bins, the material is usually dispensed directly onto the conveyor using the bottom hopper. Augers can pick up materials by inserting the bottom of the screw into the top of the materials. Rail cars and trucks can dump into hoppers or rail or car tips can upend the vehicle and drop the material into temporary hoppers or directly into the hoppers feeding the conveyor. A conveyor designed to handle bulk loose solids usually consists of the conveyor and bins with hoppers at either end.

Figure 48: Conveyor Components

Figure 15: Upright Cylindrical (CAN) Tanks

Photo Interpretation Training Course

Industries**Cultural Features 243**

The belt system consists of an endless belt (rubber, composite, or metal) running on rollers. Each segment, or flight, normally runs at a slight uphill incline and dumps its load onto the next flight.

Screw systems consist of a helical inner sleeve rotating within a metal tube. The material enters at one end and is transferred through the pipe to the outflow end.

Apron or flight systems consist of metal trays carrying the material on a chain or a metal plate with transverse plates to restrain the material. The solids are deposited at the outflow as the tray tips over at the end of travel.

Pneumatic systems use a series of tubes or pipes powered by blower motors. A cyclone (conical hopper) recovers the transported material from the entrained air. These conveyors work with finely divided solids or in the recovery of dust.

**Figure 49:** Car Unloading**Figure 50:** Conveyor Unloading Systems

Photo Interpretation Training Course

Industries**Cultural Features 257**

Figure 51: Conveyor Operation

Pneumatic conveyors are typically seen as part of the dust collection system on the roofs of plants, or, as short nearly vertical conveyors feeding silos.

Hydraulic conveyors (flumes, penstocks, and some types of pipelines) use water to transport materials. The material is divided small enough that the water can move the substance.

Conveyors can also be used for the long distance transportation of materials.

In most applications of this kind, the belt conveyor is the mode of transport. These systems can run for miles. The conveyor is normally covered and placed on or slightly elevated above the ground surface. At points along the route requiring the change of direction, a small mechanical structure is placed to accommodate the direction change (bent). Additionally, numerous motor houses are placed at intervals to provide additional motive power. The long, thin covered conveyor and small structures indicate the conveyor route.

Aerial cableways are rare and consist of a set of cables supported by two or more large trestles or pylons. The typical application is the transportation of ore from the mine to ore concentration or ore loading areas. The conveyor operates by a chain of buckets riding along the supporting wire. Their capacity is fairly small, from 2–5 tons. The aerial cableway is differentiated from a series of power pylons by several factors. The aerial conveyor begins and ends at industrial areas instead of transformer yards and substations. Substations may be positioned near the termini of the conveyor to provide motive power. Additionally, the buckets tend to lose a portion of their load as they pass over the rollers at the pylons. This results in a pile of ore on either side of the pylon.

Cultural Features 245

Transportation

Pipelines

Pipelines are unique in that the material is carried directly through the pipeline, rather than in a vehicle. This means that very little human supervision is needed. Transportation is not affected by the weather, as are other systems. Liquids and gases are not the only materials that can be moved through pipelines, some solids (such as coal) are pulverized and mixed with water to form a slurry in some conveyor systems. The volume of material that can be moved depends only on the diameter of the pipe and the strength of the pumps. Pipelines are very economical for long distance transportation. Additionally, pipelines are used extensively within industrial plants for moving fluids from one area to another. Every industry dealing with fluids has an absolute requirement for pipelines. While long distance pipelines tend to be large, at times exceeding 1.22 m (48"), pipelines in industry tend to run in the range of 6 cm - 11 cm (2 3/8" - 4 1/2"). Steam pipes will appear thicker due to the insulation around the pipe.

Location

Surface pipelines will appear narrower than roads or railroads, and will have regularly spaced angular jogs that compensate for expansion and contraction of the pipeline due to temperature changes. They are distinct from and darker than the surrounding ground. Buried pipelines may be revealed by the scar in the earth, and their trace may be discontinuous. Pipelines are straight, with angular bends, but may be very gently curved. Although the alignment is straight, there will be little evidence of cuts and fills, as pipelines follow the surface of the ground. A cleared way will be present whenever the pipeline passes through a forested area. Pipelines are more likely to cross the drainage pattern than to follow it.

Pipelines on the ground surface are readily recognizable. They are straight and narrow, and make angular bends. Frequent 90° bends at expansion joints are visible.

Junctions and branching are common within industrial facilities. This makes a maze of pipes, manifolds, and valves, rendering the tracing of pipes a virtual impossibility. Underground pipelines can be very difficult to locate. Terminal facilities are composed of pump stations, storage tanks and processing facilities that are readily identified.

Pipelines within an industry are commonly elevated off the ground surface. They may be supported at intervals by concrete abutments or telephone poles. The pipelines within the complex tend to be fairly short, running from one tank to another between processing areas.

Figure 53: Pipelines

Photo Interpretation Training Course

Crossing points must be constructed where surface pipelines cross roads or railroads. At one type of crossing point, the pipeline is simply buried underground for a short distance, allowing the road or railroad to pass over it. These are easily recognized, as the pipeline disappears at the crossing point, and there is no discernible change in the road. An other alternative is to elevate the pipe a sufficient distance to allow traffic to pass under it. This is accomplished by placing a vertical jog or loop in the pipeline. The shadow of the elevated section of pipeline is very distinctive. A third method is to build a ramp over the pipeline. The ramp is usually easy to spot, as the pipeline is covered for only the width of the ramp. The shadow of the ramp may be visible.

Figure 54: Pumphouse

Pumping Stations

Gases and liquids are fluids, that is they have no definite shape and conform to the shape of their container. They move or flow in response to gravity or other forces. Gases expand to fill the space they are contained in, and can be compressed into a smaller volume. Liquids are essentially incompressible, and will maintain a level free surface if their volume is less than that of their containers. It is these similarities and differences that dictate how gases and liquids must be handled. Liquids, because of their greater density and fixed volume, flow downhill readily, while gases need to be introduced into the

Figure 55: Gas Pumping Station

Figure 56: Oil Pumping Station

pipeline under pressure to induce flow. For uphill grades, both fluids require pressurization. For short pipelines, such as those internal to a facility, the initial pressurization is sufficient to carry the material to its destination. For longer pipelines, a series of relay stations (compressor stations for gases and pumping stations for liquids) are required to overcome frictional losses and to move the material through uphill grades.

Figure 57: Water Pump Station (Domestic, Sewer, or Storm)

Both pumping and compressor stations have a small, narrow, rectangular building that houses the pumps or compressors. It may have a gabled or flat roof, but will always have ventilators spaced along the length of the roof. The building is typically of light steel frame construction. The building may be open along one side. If the pumps are powered by internal combustion engines, the exhaust pipes, with mufflers, will be visible along one side of the building. The number of pumps or compressors, and thus the lengths of the building, are proportional to the size and capacity of the pipeline.

An oil pumping station will usually have two or three small regulatory tanks with cylindrical, flat or peaked roofs nearby, as well as a pipe manifold. A gas compressor station will usually have a pipe manifold, and a gasometer may or may not be present. Water pumping stations consist of a small building housing the pumps and an elevated or tower-mounted regulatory tank. Sewage pumping stations are small plain buildings with no associated tanks. The sewer line will not be visible.

Pipeline Contents

The appearance of the pipeline does not provide much of a clue as to the material being transported. The best clues to this information are the terminal and storage facilities and relay stations associated with the pipeline. These facilities may be the only clues to the presence of a buried pipeline.

Chemical pipes run between components and the functional areas in a processing plant. They are usually small pipes that are raised off the ground surface. Look for pipes terminating at chemical storage tanks.

Gas pipelines are usually raised off the ground surface within the industrial complex. Long distance natural gas pipelines usually are buried but when not, more expansion loops may be visible. Gas pipelines are associated with gas wells (natural gas, helium, carbon dioxide), natural gas plants, and compressor stations. Also they will be present in vast numbers within most chemical processing plants.

Gasoline pipelines will be found within a refinery from those components producing gasoline. Long distance gasoline pipelines will be buried and of medium size.

Most of the pipes within a refinery will be transporting oil, specifically the crude and rundown storage areas. Long distance crude pipelines are large (several feet in diameter), require numerous pumping stations, and may have visible pipeline heaters.

Terminals

The large size and distinctive appearance of terminal facilities make them easy to identify. The storage facilities associated with the terminal are the best indicators of the contents of a pipeline, as each product has distinctive storage requirements. Since a pipeline is normally used for one-way transportation, there will be a source terminal and a destination terminal. Occasionally, a pipeline will end at a point of consumption, such as a manufacturing plant, where the obvious clues are absent. In these cases, a detailed examination of the components of the facility is required.

Source terminals can be oil or gas fields, reservoirs, rivers, storage areas, processing plants, or transshipment facilities. In any case, there will be a terminal pumping or compression station to propel the fluid through the pipeline. Terminal pumping stations are large buildings, substantially larger than relay stations. Destination terminals can be storage areas, processing plants, transshipment facilities or points of consumption. Storage facilities will also be present.

An oil terminal pumping station will have a large pipe manifold and a complex of pipes around the building. Storage facilities consist of cylindrical tanks, and occasionally spherical or spheroidal tanks.

A gas terminal pumping station will also have a large pipe manifold, but not as much pipe around the building. The building is high-roofed, and smokestacks are present. Storage facilities consist of wet or dry gasometers, but cylindrical, flat-roofed tanks may also be present.

Railroads, Ships, and Barges

An essential requirement for any industry is transportation to and from the plant. All industries require transportation of raw materials into the facility and finished products out. For this reason, industries are always located with good road, rail, or marine access. Many industries will have multiple transportation types available. The identification of road, rail, and shipping is covered in detail in other chapters. Please refer to these sections for additional information.

Many large industries have dedicated rail and truck yards or port facilities to handle the large amounts of material. Occasionally, an extremely valuable or isolated industry will also maintain its own airfield. In these cases, the airfield is normally used solely for personnel transportation or the delivery of small repair parts.

Freight terminals deal with the shipping, transshipment or receiving of materials. For packaged materials, a single-story warehouse is used. Loading platforms are present along one or two sides of the building. If material is to be stored at the location, the building can be quite large. A small building indicates that it is mainly concerned with transshipment. There must be enough room around the loading platforms for the trucks to maneuver, as well as an adjacent, normally paved, parking area for waiting trucks. Trucks and trailers will usually be present.

Bulk materials require special handling and storage. Solids are stored in silos or elevators or are piled in open storage areas. Specialized loading equipment, including conveyors and tipples will be present. Liquids and gases are stored in tanks, and special loading points, sometimes covered, are connected to the tanks by above or below ground pipelines. The presence of a parking area and trucks, which may be specialized vehicles such as tank trucks, indicates that the facility is a road terminal.

Figure 58: Liquid (Oil) Transloading Equipment

Processing Equipment

Essential to any industry is the processing equipment. This is the equipment used to hold the raw materials during whatever reaction or treatment is required to complete the process. The equipment includes vats, kettles, kilns or ovens, and an entire range of specialized tanks (thickeners, settling, and basins). Much of the equipment will not be visible since it is housed within the industrial structures or obscured within steel framework. Some industries have no visible processing equipment while others have equipment outside the buildings. In any case, a knowledge of the components can assist in the identification of the industry. Highly specialized processing equipment most often used in a particular industry will be covered in depth within the section dealing with that industry.

Kettles and Vats

Kettles and vats are tanks used to hold raw materials during chemical and heat reactions. Kettles and vats are used in the reactions involving liquid materials. Most treatment vats are enclosed to maintain even temperature and prevent the escape of the reacting chemicals. The vats and kettles are cylindrical tanks with rounded bottoms. Often the tanks are supported on a metal framework.

Figure 59: Vats

Kilns

Kilns are large ovens used to dry or calcine bulk materials. They are used also to fire or vitrify brick and other clay products. Most kilns are gas-fired but a few are electric powered. Rarely will a coal or coke fired kiln be identified. The most common type of kiln in modern industrialized nations is the horizontal rotary kiln. Vertical kilns can also be used. Some older installations (or in special applications) use a beehive kiln. The beehive (and oval) kiln is a conical shape oven used in manufacture of coke or brick (ceramics) products.

Kilns are used mainly in the earth and ore processing industries. Some of the industries include petroleum coke, cement and clay products, ore concentration, gypsum, phosphate rocks, alumina, magnesium, potassium, zinc, and titanium processing. These ovens can also be used in disposal industries for the reduction of hazardous waste materials.

Figure 60: Rotary Kiln

The rotary kiln is a long cylindrical (tank-like) oven supported at the ends and often in the middle by gears. One end is higher than the other. The length of most rotary kilns ranges from 18 – 183 m (60 – 600 ft). The gears turn the kiln to assure even heating and to move the materials through the kiln. Typically the kiln is heated by gas flames fed from the lower end of the kiln. Rotary kilns consist of two or more parallel rotary ovens with small buildings at either end. One end introduces the raw material and the other extracts the material and houses the heating equipment and a small smokestack.

Vertical kilns are large tower-like (fixed) structures. They are fired from the middle of the lower level of the oven.

Rotary driers are smaller versions of the rotary kiln used for drying processed materials. They operate at a much lower temperature, not exceeding 427° C (800° F). Often the rotary drier will be associated with a de-watering tank or sedimentation tank that removes most of the liquid before drying operations.

Figure 61: Rotary Drier

Tanks, Thickeners, and Other Treatment Vessels

Sedimentation tanks are used for the removal of suspended solids. Gravitational settling separates the denser and lighter components. Industries using sedimentation tanks include most processing industries, most notably the ore concentration, alumina, and magnesia plants.

Figure 62: Sedimentation or Mixing Tanks

Figure 63: Industrial Vats and Tanks

There are several configurations of sedimentation tanks. Dorr thickeners (or de-waterers) are the low round tanks with a central pivot for bottom scrapers. The thickener can also have a large cross-arm across the tank to support the mechanical mixers. Often the tank has an access catwalk across the tank from the edge to the central pivot. These tanks are also used in the mixing of materials. Heavier materials settle to the bottom while the lighter material is removed from the top of the tank.

Sedimentation tanks can also be rectangular with or without bottom scrapers. Often this type of sedimentation tank is used in water treatment facilities.

Support Equipment

Smokestacks and Chimneys

Chimneys, smokestacks, or waste gas stacks dispose of unwanted and dangerous gases by diluting the concentration and releasing the material away from personnel and property. The type of emission and the particular danger associated with the gas determines the design criteria for the stack. The height of the stack partially determines the construction material (steel, brick, block, or concrete). The characteristics of the effluent, i.e., temperature, caustic, or acidic properties, determine which materials are used to line the stack flue (ceramics, metal, brick, or concrete). The design must provide for an exit velocity and a wide enough base to maintain structural integrity.

Figure 64:
Smokestack

The chimney is ubiquitous to industry. Almost every processing, power, disposal, or fabrication plant has one or more stacks. The size can range from a few feet to over 1250 feet tall. Extremely tall stacks are indicators of particular industries. Examples are nuclear power facilities, zinc, and copper processing plants.

Smokestacks up to 107 m (350 ft) can be made of brick, block, concrete, or steel. Brick or block chimneys are typically have a fairly wide base and diameter in relation to height. Tall brick smokestacks often use reinforcing steel bands at the top, bottom, and at intervals up the height. The bands provide additional structural support.

Stacks more than 107 m (350 ft) are made of steel or concrete. Steel smokestacks display the smallest height to base diameter ratio. The smooth sides often show the bands where the stack sections fit together. Steel stacks are sometimes guyed to provide resistance against wind loading. In some cases, the steel smokestack is supported by a steel lattice framework for structural support.

When the chimney height exceeds 380 m (1250 ft) concrete must be used as the construction material. Concrete smokestacks are constructed with walls 20 cm (8") thick for an internal diameter of 8.5 m (28 ft) or less. For every .6 m (2 ft) increase in diameter, the wall thickness increases by .6 cm (1/4"). The ratio of height to base diameter for concrete stacks is 12-13 to one.

Figure 65: Brick
Smokestack

The primary function of the chimney liner is to protect the structural elements of the stack from the corrosive effects of the hot gases. A secondary function is to insure an adequate exit velocity of the gases, which ensures an adequate draw. Many stacks are brick lined with fiberglass or fused silica insulation between the brick and the stack. The brick lining will be supported at intervals by shelves built into the side of the stack. The shelves are made of Corbel block with asbestos seals. To protect against highly corrosive gases, steel liners will be used. These steel liners often are independent of the chimney, that is, the liner is supported at the bottom or hung from the top of the chimney.

Other liner types include independent concrete liners, independent brick liners, and the fiber re-enforced plastic liners. The fiber re-enforced plastic and brick liners are used when scrubbers are used. The scrubbers low temperature gas output results in higher levels of corrosive condensation within the stack.

Equipment found associated with smokestacks include dust catchers, scrubbers, precipitators, and horizontal flue collection systems.

Precipitators

Electrostatic precipitators are used to remove solid particles from combustion gases. This air cleaner operates by applying an electric charge, using suspended plates, to the gases passing through the flues. The solid particles then fall to the bottom of the device for later removal. Air cleaners are used to remove solids from the gases from burning coal, ore roasters, ore smelters, and steel production plants.

Gas scrubbers are also used in the removal of corrosive and dangerous gaseous materials from the waste gases by passing the hot gases through a scrubbing medium and exhausting the cooled and clean gas into the chimney.

Figure 67: Air Cleaner

Dust Catchers

Dust catchers are mechanical devices used to remove solids from air. The dust catcher operates by blowing air entraining dust particles into a cyclone. The cyclone is a cylindrical tank with a conical bottom. As the air enters the cyclone, air speed drops. This allows any entrained solids to settle by gravity to the bottom of the cyclone for later recovery or disposal.

Cyclones may be found on the roof tops of most fabrication plants. Large cyclones are found anywhere dust could pose a health or safety hazard. Dust catchers are found in lumber operations and many ore processing plants.

Flare

Flares are used for the venting and disposal of combustible gases from processing units. Flares are common in petroleum refineries, petrochemical plants, and coke plants. The flare in the simplest form is a vertical or horizontal steel pipe with an igniter. A vertical flare is situated within a cleared area, often bermed, to provide a safety zone. Horizontal flares are virtually always bermed. The ground around horizontal flares will display burn marks on the surface.

Taller flares are often supported by steel lattice frameworks around the pipe. Flares within refineries often exceed 50 m (164 ft) in height. Often the flame and smoke from large flares are readily visible.

Figure 68: Vertical Flare Pipes

Cooling Facilities

Disposal of waste heat is a major concern in industry. Almost every industry, whether it be processing, extraction, power, or fabrication, generates an enormous amount of excess heat. In order for the industry to operate at peak efficiency, some method must be used to maintain the proper temperature. A case in point is chemical reactions. For every 10° C rise in temperature, the reaction rate doubles.

Industries with direct access to large rivers, lakes, or the sea are able to use the water as a heat sink. The plant will pump water from the body into the plant. When the water is heated, it will be exhausted directly back into the water body. The system is cheap, easy, and simple. The water, in most cases, requires only the removal of debris before use. Facilities include a pumphouse and intake pipe, on the upstream from the plant in the case of rivers, and an outlet pipe, on the downstream side. In the case of lakes and the ocean, the intake and exhaust is sometimes separated by small levees to prevent mixing of the water. Sometimes the outlet is visible as the returning heated water discolors the body of water.

Sometimes an industry will build an artificial reservoir equipped with a pump-house and an array of sprayers. The heated water is sprayed into the air, is cooled, and falls back into the spray pond for recovery. This method has the disadvantage of requiring a continual source of clean and treated water to replace

Figure 70: Spray Pond

water lost to evaporation. This system works best in areas of low humidity and moderate temperature.

More sophisticated cooling systems have been developed to cool the large amounts of waste heat generated by modern industry. Most of these systems require the use of treated water, i.e., clean and free of debris, and rely upon pumps, heat exchangers, and condensers in normal operations.

Perhaps the most common system is a radiator cooling system. This is the basis for the common home air conditioner along with larger industrial versions. The system uses ammonia or freon based coolants. The coolant expands, cooling an interior exchange system. The heated coolant is pumped to the outside, passing through a series of radiator equipped coils. The waste heat is passed to the atmosphere through radiation and conduction.

The cooled coolant material is then re-used without loss of material. The system is fairly simple but only supplies moderate amount of cooling. Units range in size from very small, sized for domestic use, to extremely large. Often the radiators will be placed on rooftops to take advantage of increased air flow.

Figure 71: Radiators

Figure 72: Operation of Cooling Tower

Larger capacity industrial systems use water as the coolant. The water operates the same manner as the freon in cooling systems. Heated water is cooled outside, returns inside to provide cooling, and is pumped outside again. Various types of systems are used depending on the amount of cooling required, the availability of replacement fluids, and local environmental conditions. The exterior portion of the cooling system consists of the cooling tower and connecting piping. The heated water is pumped to the top of the tower.

The water falls down over a series of baffles that break the water stream up. This provides a greater surface area for cooling. The cooled water is collected from the bottom of the tower and returned to the interior cooling exchange systems. During operation, these systems generate steam under the proper atmospheric conditions. In fact, sometimes the cooling towers will be totally obscured.

These systems can operate using the natural draft formed as the water cascades downward and loses its heat. Alternatively, the system can operate using forced draft provided by fans. These fans are situated at the top of the cooling tower

and are often visible. Some systems use a combination of natural draft assisted by fans. These units range in size from a small American Deck forced draft cooling tower to the extremely tall and large venturi towers commonly associated with nuclear power plants. As with radiator cooling systems, these units may be located on the top of buildings. Forced and natural draft cooling towers are commonly constructed of steel framework with wood louvers and interior baffles. Increasingly, more cooling towers are made of composite plastics and plastic over steel. The large venturi towers are usually constructed of concrete. Some older towers were constructed entirely of wood.

Heat Exchangers

Heat exchangers and condensers cool or heat a fluid through conduction. Almost every processing and fabrication industry uses heat exchangers in conjunction within cooling towers or other facilities.

Heat exchangers and condensers are used in cooling of fluids by contact with water, air, or coolant materials, condensing a vapor through coolant contact, and pre-heating and reheating through transfer of heat from hotter materials.

Most heat exchangers and condensers are extremely difficult to discern on imagery.

Extraction

The removal of mineral resources from the ground is the concern of extraction industries. This includes both the mining of mineral deposits and the production of fluid resources from wells.

Exploration

Prior to any attempt at mining or drilling, exploratory work must be performed to locate and confirm the presence of a sufficient amount of material to justify the expense of the operation. These exploration activities will leave their own special marks upon the landscape. Many activities, such as seismic surveys, are applied to the search for both solid and fluid deposits.

Geophysical Prospecting

Geophysical prospecting is the measurement of various physical properties (radioactivity, magnetism, seismic, and gravitational) of the rocks below the surface of the ground. These methods are used over areas ranging from a few kilometers to hundreds of kilometers in extent. A common denominator between all methods of geophysical prospecting is the requirement for precisely locating the sites at which the sensors are emplaced and measurements are taken. This involves the surveying and establishment of lines or grids across the area of interest. Where they are visible, geophysical prospecting lines are distinctive and can be used as landmarks for navigation purposes.

Although the lines themselves are not visible, the activity along the lines will often result in noticeable scars or marks. Trees and brush may be cleared to provide a line of sight for the surveyors. Subsequent movement of personnel and vehicles along these lines can damage vegetation and leave ruts in the ground.

Seismic exploration lines for example, may extend for over one hundred kilometers along a perfectly straight line. To provide access and space to lay out the sensors (geophones), a track will be cleared along the survey line. Survey points will be marked through metal poles or pipes (and attached plaques) along the line. The survey crews will use these tracks during survey operations after which the track will be abandoned. Occasionally, these tracks may be incorporated into the local road network.

In many areas, vegetation will quickly grow back and the prospecting grids will be completely hidden within a few years. In arid areas, however, there is little vegetation, and once disturbed, the ground surface will be distinctly marked. Because the soil forming processes work so slowly in the desert, these marks may remain for many tens of years. In addition, blowing sand (and soil) will build up around the survey markers and the abandoned geophone spikes forming small hummocks.

Figure 1: Common Geophysical Prospecting Grid Patterns

In forested areas, the trees are often cleared away from the survey lines to provide line of sight for the surveyors, and to provide access for vehicles. These cleared lines will also remain visible for many years after the surveying activity has been completed.

The patterns formed by geophysical prospecting lines vary from isolated linear features to grids or networks of linear features. Rectangular and radial patterns are common. The lines are perfectly straight, no matter what the terrain is like, and do not have logical starting and ending points. This helps to distinguish them from tracks and trails. Figure 1 illustrates some common geophysical prospecting patterns.

Prospects

Before large scale mining operations start a prospect is excavated. This is a small exploration mine intended to determine the extent of mineralization. If the prospect finds an economic ore body, the operation will be expanded to full scale, long term mining. Otherwise the area will be abandoned.

The typical prospect is a horizontal or vertical shaft mine. Small tailings (spoil) piles will be next to the mine entrance, usually on the downhill side of the operation. A prospect will not require more than minimal road access to the mine since ore will not need to be transported or processed at the site. If the site is abandoned, it will quickly become overgrown with vegetation.

Exploration Drilling

Before development wells are drilled, exploration (wildcat) wells are drilled to determine if the area has sufficient resources to justify further operations. If the resources are present, additional wells are drilled and the area becomes a producing field, otherwise the well will be plugged and abandoned. The same drilling equipment is used whether the well is for exploration or for development. While exploration wells are extensively used for oil and gas, mineral exploration also utilizes drilling (using smaller drill rigs) in the search for ore deposits.

Mining

Mining operations are classified by the method in which the materials are exposed and removed. Where the deposits are near the surface, the overlying material (overburden) is removed prior to the mining of the deposit, creating an open excavation. Where the depth to the deposit makes this method impractical, a tunnel (adit) or a shaft is dug to gain access to the deposit, and the mining is done underground.

Unless the mine can be linked to a nearby processing industry, it is nearly impossible to identify the ore being extracted.

Open

Open Pit

Open pit mining is used when the ore body is close to the surface and in a massive body or in thick layers. In the typical open pit mine, the rock is removed in stepped excavations (benches) resulting in steep cut sides (shear walls) arranged in a distinctive spiral pattern. These mines are large, sometimes several kilometers wide and more than a hundred meters deep.

Tailings (overburden) will be stored in large open piles. Ore may be stored in open piles, bins, or silos. There will be minimal (or no) buildings at the mine. Most open pit mines use explosives, so powder houses will be located at or very near the mine works. Drill rigs for drilling explosive shot holes will also be present.

Figure 4: Open Pit Mine

Figure 5: Quarry

Most of the equipment will be for handling the rock and ore and will consist of power shovels, draglines, mining trucks, front loaders, mine cars, and various conveyor systems.

Quarries are specialized open mines for the extraction of building materials such as sand, gravel, and stone. Processing for the extracted material consists of crushing, grinding, and sorting. Clay pits could be considered a form of quarry.

Barrow (borrow) pits are for excavation of fill materials. Such operations are found close to highways and railroads and usually parallel the route. Barrow pits will occur close to overpasses, fills, and causeways. Often the barrow pit will become a small lake after the required material is removed.

Quarries and barrow pits do not have tailing piles (except for dirt removed from the surface of the excavation) associated with them.

Figure 6: Strip Mining Operation

Strip Mines

Excavations of ores at shallow depth frequently take the form of strip mines. The overburden is fairly thin and the ore body occurs in thin beds. Area strip mining takes place in level and gently rolling terrain. Contour strip mining occurs where the terrain is steep.

In area mining operations the overburden is removed and transferred to previously mined areas. This results in a series of long narrow strips of parallel furrows. The operation continues until the ore thins or the overburden thickens. When the overburden becomes too thick, the mining is often continued via horizontal shaft (bank) operations.

In conventional contour mining operations the spoil is simply pushed over the downhill side of the bench, resulting in a series of wide fairly level ledges. In valley fill operations the mining proceeds laterally along the bench. A suitable low spot or valley is selected along the bench and the spoil is pushed over the side at bench height resulting in long narrow nearly flat ledges. In mountain top leveling mining the overburden is removed to the adjacent valley. This results in flattened hilltops, shallower valleys and a reduction in the local relief.

In haul back operations the spoils and overburden are moved laterally along the bench to the adjacent previously mined area. Once the operation has moved on, the land will be reclaimed and replanted. When reclamation is complete the area will very nearly regain its natural appearance.

Most equipment found at strip mines will be for material handling. Power shovels and draglines are used in mining operations. The draglines can be very large, sometimes over one hundred meters tall. Bulldozers and front loaders, along with mining dump trucks are also common equipment found at these mines

Figure 7: Mining Equipment Consisting of Ore Transporter and Dragline

Figure 8: Placer Mining Operation

Placer

Placer mining is the extraction of disseminated ores from alluvial and glacial deposits. Placer mines are found along river courses. The deposit is excavated by digging,

dredging (using bucket, screw, or suction dredges), or water cannons. The ore is separated from the deposit by washing and manual inspection, and the spoils are returned to the excavation.

Figure 9: Dredge Types

Except in areas where large scale dredging is being performed, there is little scarring of the mined area. Large scale operations often leave scars similar to area strip mines. Sometimes the natural drainage will be disrupted to the point where it is realigned.

The presence of washing equipment such as sluice boxes, pumps, pipelines, and conveyors are indications that placer mining is occurring.

Peat Cuttings

Peat is an unconsolidated deposit of semicarbonized plant material occurring as false bottoms in bogs or fens. This organic material is high in moisture content but burns freely when dried. Peat is mostly found at high latitudes.

Peat is mined by cutting blocks of the material out of a ditched and drained bog, resulting in a distinctive rectangular pattern of shallow pits. The peat is very dark (due to high moisture and organic content) and is easily recognized when piled near the excavation.

Underground

When the ore deposit is situated too deep, or it is disseminated in narrow veins and seams, open mining techniques are not economical. In these cases the mining operations are carried out totally under the ground surface. Because the operation and equipment are underground and out of sight, and the mine is often located in mountainous terrain, it is difficult to identify the location of the mine. However the presence of an ore concentration plant and low capacity rail lines leading to the plant from the mine are useful indicators of underground mines.

Mine head equipment and signatures vary depending on whether the entrance is through a vertical shaft or a horizontal shaft. Both types have in common the

requirement for adequate ventilation. Block-like or cylindrical air shafts may be visible in the immediate area. Additionally tailings piles will be situated near the mine entrance. A store of timbers, used for shoring up mine walls and ceilings, will also be located near the mine.

Figure 10: Horizontal Shaft Mine

Horizontal Shaft

Horizontal (bank) mines occur in mountainous areas where the entrance can be placed at the same elevation as the deposit being mined.

The actual entrance (adit) is a tunnel into the side of the hill with a low capacity road or rail line leading to it. Usually mine cars (small rail cars operating on narrow gauge) bring the ore from the mine to a tipple or skip where the material is dumped into hoppers or bins. From here the ore is transported by way of trucks or rail to a processing plant.

Vertical Shaft

Vertical shaft mines can occur in any type of terrain, and are constructed when the deposit to be mined cannot be reached by a horizontal shaft. The typical vertical mine has an 'A' frame latticework headframe over the shaft. The headframe can be substantial in construction, very tall, with lattice supports bracing the main structure. The large pulley may be visible at the top of the structure, or the entire structure may be enclosed.

Collocated with the headframe will be the winch house (for the lifting mechanism), the compressor house (and bullet tanks), various small buildings, and the ore

Figure 11: Shaft Mining

Figure 12: Vertical Shaft Mine

skip or tippie. The ore will be dumped to hoppers or bins and then transported to the processing facility.

Ore Concentration

In order to reduce transportation costs, the ore is often concentrated at or near the mine. First the mined material is reduced in size. Then differences in the physical properties (natural and induced magnetism, specific gravity, solubility, and wettability) are exploited to separate the mineral and the gangue (worthless rock). Afterwards the mineral is stockpiled and shipped on for further processing.

All or most of the associated equipment may be housed within a concentrator building. This building will have a characteristic stepped appearance with numerous roof vents.

Figure 13: Ore Concentration Processing Plant

Initially the ore is greatly reduced in size in the primary and secondary crushers (gyratory, disc, and roll crushers). The material is then sent by conveyor to the tertiary (fine) grinding where the ball and tube mills reduce the mineral to flour like consistency.

The ore is mixed with water before being concentrated. The ores may be concentrated through a flotation separation method. This method uses rows of flotation tanks to separate the ore. The mineral rises to the top of the tank and

Figure 14: Flow of Concentration Process

is skimmed off while the tailings settle to the bottom. In a similar method, heavy fluid separation, the ore sinks and the tailings float. The tailings are sent down the launder to the tailings dewatering tanks where the water is recycled and the tailings sent to the tailings pile.

The skimmed ore concentrate is sent to the thickening (settling) tanks where the ore concentrate settles out and is recovered for further processing. After concentration has occurred, the mineral is sent to the filtering and drying building (stacks and vents are visible) where excess water is removed and the material is readied for shipping.

Gravity concentration may be used where the ore is passed through a series of sluices (inclined open-end troughs) submerged in water and vibrated. The heavy ore minerals settle to the bottom and the gangue is washed away. Other concentration methods include magnetic separation, cyaniding (precious metals dissolved and then precipitated), and amalgamation (mercury coated copper plates dissolve metals that are later distilled).

Figure 15: Ore Concentration Flow Chart

Coal is processed in a different manner. First a series of breakers separates the coal from the rock. Then crushers, screens, and classifiers reduce the coal to the necessary size and consistency. The coal is then washed and dried and shipped. In some cases, the coal is liquefied and pipelines are used to transport the coal.

Material from quarries is sent to a classifier, which sorts the material by size. Branching conveyors then deposit the material in various storage piles, hoppers, or silos.

Silos, bins, and warehouses will store the material at both intermediate stages and final product stage. Reagent storage will be in enclosed cylindrical tanks.

Figure 16: Coal Mine and Classification/Sorting Plant

Wells

Wells are used to extract resources from the earth which are not accessible through mining operations. Wells produce gases such as petroleum gas, helium, and carbon dioxide; liquids in the form of water, oil, iodine, and bromine; and products of solution mining such as sulfur and salt. Wells are also used for the disposal of semi-solid and liquid waste products.

Oil fields are the most complex type of well system to address. Water and mineral wells can be considered a subset of well drilling methods. The type of equipment can be identified by its association with one of the four interrelations of production. These are drilling operations (and associated completion operations), actual production through the well (including maintenance and eventual abandonment), field processing of the petroleum, and gathering and field storage of petroleum.

Shallow water wells may be dug rather than drilled. In agricultural areas, water wells are near housing or livestock holding areas. Often the availability of water determines where the farm or ranch is situated. Often livestock tracks and footpaths lead to a well. These wells may have walls, holding tanks, and some mechanism to bring water to the surface.

Figure 17: Dug Water Well

Drilling

Almost all drilling is done using rotary drill rigs. Rotary rigs use a bit attached to the end of a rotating string of drill pipe. In some cases the drill string remains stationary and downhole motors turn the bit. This method is used mostly for deep or highly deviated holes.

Figure 18: Rig Types

Figure 19: Standard Derrick (Rig) Components

The rig is a modified 'A' frame tower, called a standard derrick, which is assembled at the location, used to drill the well, and then disassembled. A second type is a mast rig that was assembled at a factory and then moved as one piece from location to location. Both are referred to as "derricks" or "rigs". Rigs can exceed 50 meters in height. The derrick is set on top of a rig substructure that provides a stable platform for drilling, clearance for work under the rig around the well-head, and room to accommodate pressure control equipment over the wellhead.

The rig provides the support for a set of pulleys and blocks that handle the drill pipe and casing pipe during drilling. There will be a work platform (monkey board) for the derrick man and storage racks (fingerboard) to hold pipe. Attached to the front of the rig are ramps ('V'-door) to pull material up onto the rig floor and working platforms (catwalks) to stage pipe. Pipe racks will be placed on one or both sides of the catwalk. At the back of the rig will be the drawworks with the winch to power the blocks.

Motive power is provided by a series of two to four prime movers, usually diesel engines, mounted on box like skids. Transmission is by mechanical linkage to the drawworks, or electrical generators may transfer power to electrical motors.

Most rigs drill using drilling mud, so there will be a set of steel mud pits, hoppers, mud house, a shale shaker, desilter, desander, and a degasser associated with the rig. Additionally, expect to find fuel and water storage, offices, and bulk storage. In a busy field numerous rigs may be conducting operations at the same time.

A water well rig is a much smaller version of an oil rig with the same type of equipment, but it is usually self-contained on a truck chassis.

Onshore

Prior to setting up the rig, the site is cleared and leveled. If required, improved roads are built and sometimes gravel, shells, or boards are applied to provide easy access. Very important wells, or those expecting to accommodate operations for several years, may have a hard surface pavement applied.

A water source is located or, if necessary, a water well is drilled. Reserve (mud) pits are

Figure 20: Well Configuration

dug for mud storage and waste fluids. The cellar (area immediately around the wellhead) is dug out and faced, usually with boards or poured concrete.

Then the rig will move in and drill the well. Several times during the drilling process a protective pipe string (casing) is installed in the well. This casing serves to keep the bore from collapsing and protects the ground water from contamination. Several strings of decreasing size casings are run as the well goes deeper.

If a pay zone is not found the well is plugged. If pay is found, the drilling rig may complete the well (conduct formation perforating, set tubing, and assemble the wellhead pressure control or pumping equipment) or the drilling rig is removed and a smaller completion derrick is moved in to perform well completion.

After the last string of casing is run and cemented in place, the producing formation is perforated. That is, a series of shaped charges are lowered into the well and detonated to punch holes through the casing, cement, and into the formation. Then a string of production pipe (tubing) of small diameter is placed into the well.

If sufficient gas exists in the formation, the well will flow on its own, and production will occur through a Christmas tree assembly for high pressures, or through a simpler orbit valve for low pressures. If the well will not flow on its own, a downhole pump is placed at the bottom of the tubing, sucker rod (solid steel rods to provide mechanical linkage between the pump and pump jack) is attached to the pump, and a pump jack (or other type of pump engine) is assembled over the well head.

The final wellhead consists of casing head flange, pressure control equipment such as valves (in the form of a low pressure orbit valve, a stuffing box [for pump jacks], or higher pressure Christmas tree), and a series of pipes through which to produce the well fluids.

Water wells can have a windmill placed over the wellhead, a hand operated pump is sometimes used, or a pump house will totally enclose the wellhead.

Figure 24: Pumpjack (Walking Beam Pump)

**Figure 25:** Water Well Pumphouse**Figure 26:** Windmill

Offshore

On land, the rig, the rig substructure, and all the ancillary equipment rests directly on the earth's surface. Offshore, a drilling platform is provided to support the rig and all the ancillary equipment. The water depth and the number of wells expected to be drilled determine the type of offshore platform to be used. With the exception of the permanent platform, once the wells are completed and producing, these rig drilling platforms are moved away to another location for more drilling activity. That is, they are not of a permanent nature.

For very shallow water, normally bays and lakes, a self-contained drilling barge is used to conduct drilling and completion activities. During production the well-head equipment will either rest directly on the bottom or will be placed on a small permanent platform.

**Figure 27:** Offshore Drilling Platform (Rig) Types

Figure 28: Submersible Drill Platform

A submersible drilling platform is used in shallow water. This rig is floated on buoyancy tanks to its location where water is pumped into the tanks, the drilling platform sinks, and drilling operations are conducted with the drilling platform resting directly on the seafloor. Most of the mobile rigs have a 'keyway' (slot) cut out in the area of the platform under the drilling rig that is large enough to accommodate a production platform. If a production platform is planned, it will normally be erected prior to the drilling operation commencing. Otherwise production wellhead equipment is placed on the seafloor.

In moderate depth water a small production platform is built (permanent platform) and a tender (small ship or other vessel) will provide support functions such as drilling mud and living quarters. A movable drill rig will be placed on the small platform to drill the required number of wells.

Permanent platforms are used in shallow to deep water. The drilling rig and its ancillary equipment are contained on the platform. After drilling operations are completed, the rig is removed but the platform remains and provides all the production equipment needed for normal operations. Numerous wells, sometimes as many as thirty-six, are drilled from one platform.

Figure 30: Permanent Platform

Figure 29: Drilling Platform and Tender

The jackup drilling platform rig is used for water depths less than 250 feet (depth determined by maximum extension of legs). The platform is floated to its location, then large legs are cranked down to lift the platform clear of the sea. This type of platform uses three (or four) hollow or lattice work legs to support the platform.

A drill ship can operate in any water depth that is at least deep enough for the vessel's draft. This type of vessel is normally used only for exploration wells, because of its high operating costs, and another type of drilling platform is used for developmental wells.

Figure 32: Drillship

The semi-submersible drilling platform (floater) has large buoyancy tanks. The platform is moved to its location, the tanks are flooded, and the rig is either anchored or conducts station keeping while the well is drilled. This rig is usually used for fairly deep water. The semi-submersible rig is characterized by numerous anchor lines and winches on the vessel's decks. The presence of the anchors differentiates the semi-submersible from the submersible platform.

Production from wells in deep water is usually accomplished from subsea production platforms, these platforms are placed on the sea bottom and are not visible.

Figure 33: Semi-Submersible Drilling Platform

Offshore wells are drilled and completed the same as land wells. One notable exception is that pump jacks are not used in offshore operations. If a well does not flow on its own, a gas lift (gas injected from the surface to the production zone and allowed to expand to move the oil uphole) is utilized.

Production

Production from a well is not a simple matter of pumping the well fluid to the surface. Most types of wells require some in field processing to remove impurities. This occurs at the wellhead or at a central location connected to several wells. Common impurities removed at oil and gas wells include sand, silt, salt water, sulfur, and gas (either unwanted petroleum gas or hydrogen sulfide gas).

Gathering and field storage are also part of the production process. Here fluid from several wells is moved to a central location for in field processing and storage prior to transshipment to users or a refinery.

Oil & Gas

Most petroleum wells have a maintained road leading to the well. The road may make a loop around the location. Typically some treatment equipment is located at the well or nearby. Wells with pump jacks are the easiest to identify because of the large pump assembly over the well. Wells with only pressure control equipment over the well are harder to detect.

After the fluid reaches the surface, the gas is separated from the oil using a gas/oil separator. The gas/oil separator is a horizontal or vertical tank with chambers to reduce flow turbulence, allowing the gas to separate and rise to the tank top where it is drawn off. Unwanted gas is burned at a flare. If there is enough gas for gas production, it is compressed and sent through a pipeline for further processing.

Figure 34: Oil and Gas Production Field

When the well fluid reaches the surface, it also contains unwanted material, most of which is in the form of salt water. After passing through the gas/oil separator, the well fluids are sent to the flow tanks (50 to 250 Bbl) near the wellhead. Here water and some solids are removed. The separated water is moved, usually by gravity, to water tanks (modern water tanks are plastic) for eventual disposal.

The oil is moved to lease tanks (large steel tanks) for removal by trucks or injected into pipelines for transshipment. The gas and oil are handled through separate pipelines in the gathering system.

Additional lease equipment includes heater treaters (to handle paraffin) and accumulators (to handle gas).

Numerous pipelines are associated with petroleum wells. A 2" to 4" pipeline connects the well to the flow tanks and the ancillary lease equipment. A series of 4" to 6" pipelines connect the flow tanks to batteries of lease tanks. Gas compressor stations or oil pump houses inject the petroleum into larger pipelines for transshipment to refineries. These pipelines vary greatly in size.

Figure 35: Gas/Oil Separator (GOSP) and Gathering System

Water

Limited volumes of water are produced from a dug or drilled well by means of buckets or small hand operated mechanical pumps. These wells have a minimum of wellhead equipment. Sometimes the well is covered by a small building (or covered by a shed roof) and is fenced. A small holding tank, usually open, is often associated with small low volume wells. For agricultural usage a larger volume is required and often windmills are used to drive pumps at the well.

Larger volumes and pressure requirements require mechanical pumps to move the water. Most of the time the pumps are contained in a pump house. The pump house may have power lines leading to it or exhaust stacks may be visible. In large scale operations the water is transferred through a pipeline to a water treatment facility.

Most water wells are dispersed throughout an area. A small well field of 15-20 water wells sometimes provides water for cities.

Other

Helium and carbon dioxide are also produced from wells. These wells are characterized by a small field of wells, compressor houses, and high pressure storage tanks. Because of the low volume of gas produced, the field will not have a pipeline system to transport the gas.

Solution mining is used for production of salt, sulfur, bromine, iodine, and other minerals. Solution mining wells require large amounts of fluid to transport the dissolved solids. Often an injection well near the production well is used to force fluids through the formation to dissolve the minerals. A complex of large pipelines (8" or larger), a series of large surface pumps, a lack of wellhead ancillary equipment, and an association with a processing plant is an indication of solution mining.

Another type of well is a disposal well. This is a well used to dispose of waste or unwanted material. In an oil field, for example, a disposal well is used to dump the large amounts of salt water generated by the wells. Industries also use disposal wells to rid themselves of waste chemicals. The typical disposal well has several storage tanks or open sumps (to temporarily hold the waste), a small pump house, a small office building, and a set of scales to weight tank trucks. The disposal well often is isolated from other wells.

Disposal

The disposal of waste products from everyday living and industrial plants is an ever-growing problem for any industrial nation. An enormous amount of waste is produced daily and this material must be handled in some manner. Figure 1 displays the amount of combustible waste generated in the U.S. in 1974. This totals 624 million tons of waste annually. This does not include inert materials such as slag, tailings, and recoverable metals and glass.

WASTE SOURCE	% TOTAL WEIGHT	10 ⁹ KILO-GRAMS
URBAN REFUSE AND SEWAGE	16.3	92
MANUFACTURING AND PROCESSING	5.8	33
AGRICULTURAL	77.9	441

Figure 1: Combustible Waste U.S. (1974)

Solids

Tailings

Tailings are waste earth or rock excavated during mining operations or the spoil (refuse) material separated during processing operations. The tailings generated during mining and processing represent an enormous amount of solid waste.

The overburden from surface mining operations is sometimes used in reclamation activities, however it is not economical to replace all the excavated material.

Mining operations usually dispose of tailings by dumping the rock clear of the excavation. A belt or bucket conveyor, or dump trucks are used to transport the material to the disposal area (often a hillside). Over time, the tailings pile grows very large, at times exceeding 50 meters in height. The tailings have a different tone and texture from the surrounding area. Another key to aid in differentiating tailings piles from ore piles is the obvious lack of facilities for retrieval of the material from tailings piles.

CITY TRASH				

Figure 2: Tonal Characteristics of Solid Waste Material

Because the actual mineral content can be so low, more than 99% of the ore-bearing rock extracted may be gangue (rock of worthless mineral content). The tenor (grade or percentage) of economically recoverable minerals can be less than 0.02%, that is 200 grams of mineral per 1000 kilograms of ore. Most of the spoil from ore processing is in fluid form.

Processed spoils are often dumped in sludge ponds. The launders from the dewatering tanks carry the excess material to the tailings pond, where the water evaporates, leaving the waste. When the ponds fill, another pond is built to handle waste material.

Figure 3: Mine Tailings Pile

Figure 4: Tailings at Magnesium Reduction Plant

Slag

Slag is the solid clinker by-product (dross) of ore and metal processing. In order to produce one ton of metal, more than 5,000 tons of ore may have to be processed. Other than dumping, there is no economical method available to dispose of this material.

Normally a belt or bucket conveyor transports the material to the disposal area (often a hillside), where it forms a large pile. Earth moving equipment, rail cars, or trucks may also transport the material. Slag is dumped in long parallel rows to

Figure 5: Slag Pile at Zinc Plant

one side of the industrial area. The lack of a mechanism for retrieval differentiates slag piles from ore stockpiles. Pure clinker material (without toxic elements) is used to manufacture building blocks (cinder blocks). In these cases, facilities to move the slag to the manufacturing plant are present.

Scrap Yards and Wrecking Yards

Scrap and wrecking yards are used to reclaim useful material, usually metals (in the form of discarded automobiles), but reclamation of ceramics and glass is possible. The scrap material is brought to the yard, the material is sorted, and then stored (in large open storage) until the material is resold and removed. Often, metallic scrap yards are near metal processing industries. Using scrap metal is cheaper than processing raw ores.

Figure 6: Steel Scrapyard at Steel Plant

The open scrap storage area has a distinctive appearance due to the non-uniform size and shape of the scrap materials. Tonal differences are apparent from both shadows and non-uniform color. Wrecked and scrapped vehicles are easily identified, since the vehicles are piled on top of each other. Also, there are no provisions for easy removal of the vehicles (i.e., minimal driving lanes in the yard). Within the yard, overhead gantry and rotating cranes (sometimes equipped with electromagnets rather than buckets), and various specialized vehicles are used to move material.

One or more open sided sorting buildings can be present. Sorted material is stored within the buildings prior to transport, or the material may be stored in bins.

Landfills

The most popular and economic method of disposal for solid waste is the landfill. Usually the landfill is located near the waste producers (i.e., city), but in recent years trash has been transported by road, rail, and barge enormous distances due to the scarcity of suitable dumps. The typical operation involves trucking the trash to the site (in waste disposal and dump trucks), dumping the trash into a prepared area, and backfilling (covering) the trash with dirt (for sanitary and esthetic reasons). Leaching of effluent from the landfill into the water table is a major concern. Most modern landfills have clay or plastic lining to prevent leakage and monitoring wells to detect leaks.

The landfill covers extensive acreage, and unless care is taken, the trash will blow for some distance from the dump. The trash will display a range of colors, tones, sizes, and textures. Material handling is in the form of bulldozers, both to move and level the trash and backfill dirt (usually piles of dirt are found in the area). A well-maintained transportation access is a vital necessity for the landfill.

Incinerators

An alternative to landfills is the incinerator. The waste heat from municipal incinerators can be used for power generation and steam heating. Solid waste material is stockpiled, sorted to remove large non combustible items, and shredded. Processing of the shredded material includes air sorting (a vertical or horizontal sorter uses gravity and air flow for separation) and reclamation of materials. Waste heat is used to dry the trash. Liquid waste can be injected into fluid bed combustors along with solid materials.

The incinerator is a tall building with prominent truck ramps. The ramps

Figure 7: Incinerator Operation

Figure 8: Trash Incinerator

usually enter opposing sides of the building. Fuel sources (other than trash) are not apparent. Overhead cranes and material handling equipment are found at the plant. Large operations can burn enough material to run generators or steam plants for local use. In this case, transformers or steam pipes are visible.

Composting

To alleviate the load on landfills, composting the organic portion of solid waste is becoming a common disposal method. The organic material (in large scale operations) is mixed with dirt and piled in parallel rows. The material is turned occasionally, and after bacterial action, the material becomes soil. The soil is transported and used in agricultural and residential applications. The presence of earth moving equipment and dark toned, parallel compost piles (situated clear of residential and industrial areas) is an identification key.

Liquids

Isolated dwellings and small industries can use septic systems for disposal of liquid wastes. Some waste liquids are dumped directly into streams (essentially treatment is by dilution). Larger urban areas and large industrial complexes cannot rely upon such crude systems. A city will have domestic sewage from dwellings (bath, kitchen, and laundry waste), industrial sewage (waste from food, cooling, and manufacturing processes), and street waste (refuse, storm water runoff, grease, and oil). Typically, 100 gallons per capita per day is the expected amount of liquid waste produced in a city.

Sewage Treatment

Some areas of the world rely upon waste collection from individual houses for transport to a disposal site. This is not an efficient system in large urban areas. A waterborne system of pipes, pumping stations, and disposal plant is the best method for large cities.

Figure 9: Sewage Outfall Pipe

Sewerage is the process of waste removal using water as the medium. The sewerage system includes all the facilities for collection and transportation (sewer pipes), treatment (sewage disposal plant), and disposal (landfill, incinerator, or irrigation methods) of sewage. Modern cities use a system of sewer pipes and pumping stations to transport waste. Sometimes separate (dual) systems of sanitary and storm sewers keep storm runoff from overburdening the treatment facilities.

Figure 10: Sewage Treatment Processes and Components

Purification of sewage is the oxidation of sewage by bacteria to its basic mineral components. In low flow systems, sewage can be dumped directly to the stream (disposal by dilution) without adverse effects. Higher flow requires more treatment if upset of the stream system is unacceptable.

The simplest form of treatment is natural purification where the solid and liquid components are separated by sedimentation, the liquid (effluent) is pumped to the stream and the solids are treated. Another method is irrigation, where the effluent is sprayed over porous ground and allowed to evaporate and percolate into the soil. In order to prevent stream pollution from large quantities of sewage, a more complex treatment is necessary. Mechanical, chemical, and biological means are used to reduce organic content, remove solids, and neutralize chemical contaminants. A sewage treatment plant consists of numerous water-filled basins and very few buildings (relative to site size).

Figure 11: Coarse Solids Removal

Primary Treatment

Primary (partial) treatment consists of separating and treating the solid portion of sewage leaving a partially treated effluent. The initial process in treatment is the removal of coarse (and indigestible) solids. The indigestible solids are removed by bar screens (coarsest objects), comminutors (grinding of remaining large, decomposable materials), grit chambers (removal by settling of heavy solids), and grease-removal tanks (skimming off oil, fat, and grease). The process is carried out in a single structure, usually a long, narrow, open concrete tank nearly flush with ground level.

The next stage is the removal of fine solids. Commonly this is accomplished using either primary sedimentation basins or Imhoff tanks. Primary sedimentation basins are rectangular or round, open, concrete tanks nearly flush with ground level. They are

Figure 12: Mechanical Bar Screen

equipped with sludge scrapers to direct the settled sludge into a bottom discharge well. The basins may have surface skimmers for grease removal.

Chlorine-contact chambers are used to treat the effluent. Turbulent water and chlorine are mixed in these long, narrow, baffled chambers, killing any remaining bacteria.

It is necessary to treat the raw sludge from the primary sedimentation basins because it rapidly decomposes. Stabilization is accomplished by digestion. Here bacteria are allowed to act on the organic content. The end product is a stable material that is incinerated, used as soil conditioner, or dumped. Rectangular or circular open top digestors are used in warmer climates. In cooler climates (warmth is needed for the bacteria to operate) covered circular digestors are used. These tanks may be earth-bermed to conserve heat. In both types, raw sludge is introduced into the tank and allowed to stabilize. The treated sludge sinks and is removed from the tank.

Figure 13: Comminutor

Figure 14: Primary Sedimentation Tank

Figure 15: Circular Sedimentation Tank Arrangement

Figure 16: Rectangular Sedimentation Tank Arrangement

Photo Interpretation Training Course

Figure 17: Chlorine Contact Chamber

Figure 18: Fixed Roof Covered Digester

During the digestive process, methane gas is released. In covered digestors (roof may be fixed or floating top), the gas is collected, held in a gas-holder for use as fuel, or sent to a flare for disposal.

Imhoff tanks act as a primary sedimentation basin built over a digester. An Imhoff tank is a bi-level septic tank that requires 6 to 9 months to process the sludge. Because of the long time required for processing, several Imhoff tanks must be used. They are found clustered in a rectangular arrangement.

Water must be removed from the digested sludge before disposal. Several methods are possible. The sludge is sent to a sludge lagoon where the water evaporates or drains into the soil. When the sludge is dry, it is removed by scrapers. Sludge drying beds are a system of low, rectangular basins (one meter deep) with drain tiles under 20 cm. of gravel and 10 cm. of sand. The sludge flows out over the bed, the water drains, and the dried sludge is removed. In colder climates these beds are enclosed by glass structures resembling greenhouses.

Figure 19: Typical Earth Covered Digester

Figure 20: Rectangular Open Digester

Figure 21: Imhoff Tank

Figure 22: Imhoff Tank Arrangement

Figure 23: Sludge Drying Beds

Figure 24: Elutriation Basins

Figure 25: Multiple Hearth Furnace

Another method involves washing the sludge with fresh water in elutriation tanks (narrow, open, rectangular basins), conditioning with chemicals to coagulate the sludge particles, and then removing water with a vacuum filter. The vacuum filter is contained in a building between the elutriation tanks and the incinerator. Sludge dried in a vacuum filter can be incinerated for final disposal.

Secondary Treatment

Secondary (complete) treatment for the solid component of sewage is identical to the processing of the sewage by primary treatment systems. Additionally the effluent is treated by oxidation, filtration, and chlorinating processes similar to water purification. The result of secondary treatment is a completely treated effluent with practically all solids removed and treated.

For secondary treatment, the next step is the removal of colloids and bacteria (using trickling filters or activated sludge tanks) from the effluent. Filtration is done by trickling filters, which are composed of layers of crushed stone and sands (giving a dark tone to the tank) over which the effluent is sprayed.

The sewage percolates downward, leaving behind organic matter, which is stabilized by bacterial action. The resulting stabilized soil is carried out with the effluent and sent to secondary sedimentation tanks.

Rotary trickling filters are large, circular, concrete tanks with two or more rotating sprinkler arms that operate continuously. Fixed nozzle trickling filters are large,

Figure 26: Rotary Trickling Filters

Figure 27: Fixed Nozzle Trickling Bed

open, rectangular concrete structures (with two dosing tanks nearby). The dosing tanks collect the effluent, and when full, discharge the effluent over the filter in discontinuous operation.

Alternately, activated sludge tanks may be used. Activated sludge tanks (oxidation beds) are long, open rectangular, concrete tanks arranged in parallel banks of two or more units. Here, the effluent is mixed and agitated by compressed air or rotary paddles (the foaming sludge aides identification). The resulting coagulated mixture is sent to the secondary sedimentation basin.

The secondary sedimentation basins operate in a manner identical to the primary sedimentation basins. Here, the final separation of coagulated solids occurs and the sludge is sent back to the digestors.

Modern plants treat the effluent with lime, metallic hydroxides, or ion exchange systems to remove phosphate and polyphosphate compounds. This treatment reduces unwanted vegetation blooms around the waste water discharge pipes. Chlorine-contact chambers kill any remaining bacteria.

Tertiary Treatment

In some areas, increased environmental concerns have mandated additional waste treatment. These tertiary treatment systems are used to reduce the BOD (biological oxygen demand). The result of treatment is lower concentrations of ammonia, nitrates, phosphates, heavy metals, and toxic organic compounds. Another concern is reducing pathogenic bacteria, enteric viruses, protozoan cysts, and helminth eggs that, if left untreated, would contaminate the water. The tertiary treatment facilities are similar to potable water treatment facilities.

Tertiary treatment plants are expensive to operate. Common treatment systems include reverse osmosis and dialysis, ammonia stripping (air forced through effluent), coagulation, filtration with sand and coal, activated charcoal treatment, and disinfecting with ozone or chlorine treatment. The final effluent is stored (for three weeks) in lagoons or used to irrigate grass beds.

Figure 28: Fixed Nozzle Trickling Filter Bed

Figure 29: Activated Sludge Tanks

Industrial Liquid Waste Treatment

Most industrial plants pretreat waste water prior to releasing the fluid to the sanitary sewer system. This must be done since municipal systems cannot handle the toxic chemicals and dissolved metals from industrial processes. Some plants will treat waste water and recycle the treated fluid.

Treatment from most industrial process consists of precipitation, reduction, oxidation, coagulation, and flotation methods. After this initial treatment in various clarifiers, thickeners, and flocculation units, the waste is treated as sanitary waste material. Some industries dispose of waste through irrigation and evaporation methods.

Gases

Gases resulting from sewage treatment and industrial processes can be vented directly to the atmosphere when the concentration is low and no health hazard is feared. When the gases are combustible, they can be stored, usually in a gasometer, and used as fuel.

Figure 31: Vertical Flare at Oil Refinery

Figure 32: Horizontal Flare on Jackup Oil Platform

Unwanted combustible gases are flared. The flare can be horizontal when the flared material is low in volume and flare use is intermittent. Large scale burning on a constant basis requires a tall vertical flare. This keeps the dangerous gases and fumes of combustion far enough from the ground surface that no health hazard is posed. A flare is simply a pipe, usually equipped with an electrical lighter, which can be free standing or supported by latticework. The flare is situated clear of other structures and is often centered in a bermed area. Petroleum refineries, sewage plants, petroleum wells, and coke plants use flares.

The exceptions to large vertical flare systems are on offshore petroleum drilling and production platforms. Here, to provide clearance for rotary aircraft, the flare is boomed out horizontally from the platform.

Power

Introduction

Power generation consists of the production and distribution of electric power. The power plant provides the method to convert fuel to mechanical energy, which drives the generators and produces electricity. The main methods of generation are thermal energy (using steam driven turbines), hydroelectric (using water pressure to drive turbogenerators), and internal combustion (direct conversion of mechanical to electrical energy).

Figure 1: Electric Power Sources

A system of substations (transformer and switching yards) and power lines (suspended from transmission towers or pylons) distribute electricity to the user. The distribution system allows the connection of numerous power plants and subscribers. This allows the network to minimize variations in load demand on any one power plant.

The size of the plant varies by its intended use, i.e., whether the plant supplies the primary power (base load) to a region, or if the plant provides intermittent power during peak power demand. Fuel quality and type also influence plant size. Typical output for a large base load plant using coal is 1200 megawatts and for a hydroelectric plant 825 megawatts. For a peak load plant, designed to handle increased load demands, the power output ranges from 200-600 megawatts.

Figure 2: Electricity Flow from Power Plant to Consumer

Power Transmission

The power distribution grid starts at the power plant and ends with the subscriber. High voltage electric current (45 kilovolts or more) can be transmitted long distances with low power losses. However, the customer uses low voltage current. A system of stepping up transformers (increasing voltages for power transmission), stepping down transformers (decreasing voltages for subscriber use), and switching stations (directing current from transmission line to transmission line at the same voltage) manipulates electricity along the transmission network.

Figure 3: Power Transmission Network

Substations and Transformer Yards

Transformer yards are extremely large transformer complexes found at power plants. These yards are a complex of large transformers and switching networks. A substation is the complex associated with the rest of the distribution network. The basic classification of substations divides those associated with transmission of electricity (high voltage substations) from those associated with distribution of electricity to the user (low voltage substations). The type of equipment at the yard is the basis of an additional distinction. Transformer substations consist primarily of transformers and equipment related to transformers. Switching substations consist of current and voltage switches. Customer substations are substations on the user's premises and provide distribution only within a particular complex. Converter substations convert AC (alternating current) to DC (direct current). Inverter substations convert DC to AC.

A transformer substation consists of transformers (large primary transformers), circuit breakers (for over-voltage protection), disconnect switches (controlling current flow), bus bars (flexible conductors or hollow aluminum pipes to create

Figure 4: Transformer Substation

the electrical connections), shunt reactors and capacitors (to provide voltage and current to operate the equipment), current and potential transformers (used to measure voltage and current flows), and the control and protection relays.

The large, primary transformers are rectangular (enclosed) boxes. Air insulated transformers have their electrical connections open to the atmosphere. The air's non-conductive properties protect against grounding. This type of transformer requires a fence to limit access within the danger zone. Metal clad transformers have both the electrical connections and the transformer contained within a metal box. Large pipes containing a non-conducting gas, such as sulfur hexafluoride, protect gas insulated transformers from arcing. The gas pumped into the pipes provides insulation around electrical connection points and between components in the substation.

Transformer substations are usually light-toned because they are built on beds of crushed gravel or cement. They are rectangular features with a gridded or framework appearance. The primary transformer will be a solid rectangular unit (ovoid or cylindrical shapes are possible), centrally located between the high and low voltage switchyards and circuit breakers. The transformer is isolated from the general metal framework of the rest of the yard. The transformer has multiple electrical conductors attached at the top. Cooling fins provide heat transfer for the transformer. The transformer is often placed on top of a concrete pad.

Figure 5: Transformer

Figure 6: Circuit Breaker

Figure 7: Switching Substation

Sometimes it is isolated from the rest of the installation by blast walls. A control building is also present.

The switching substation consists mainly of switches and circuit breakers. The overall appearance is similar to transformer substations, but without the primary transformers. The circuit breakers and switches are cylindrical or ovoid arrangements of solid black equipment. Circuit breakers and switches have two bus bars at the top, while transformers will have multiple conductors. Additionally, the circuit breakers and switches are incorporated within the metal framework of the substation. Substations for switching, converting, and inverting usually have their primary equipment housed within a building.

Figure 8: Distribution Substation

Customer substations are small transformer units (of the metal clad type). They are associated with plants and factories.

An industry requiring large amounts of direct current (DC) uses converter substations (converting the alternating current from the power grid to direct current). For submarine cables more than 50 kilometers in length, the use of direct current reduces excessive line loss. The converter substation consists of a series of enclosed converter valves (thyristors), filters, reactors, capacitors, and transformers. A building contains all the equipment, except the transformers.

Figure 9: Converter Building

Transmission Lines and Pylons

Networks of power transmission lines, carried on transmission line pylons, transmit the electricity from the power plants through the various substations and transformer yards. These high tension lines carry the high voltage current. So called because of the stress the line conductors are placed under. For example, a 22.2 mm (.875 in) conductor is under 68600 N (15425 lbs) of stress, or around 18% of its ultimate breaking strength.

High voltage efficiently carries large currents over long distance. Low voltage loses too much current to resistance losses to be economically feasible. A network of lower voltage lines carries the electricity from the distribution substations, situated near the consumer, to even smaller pole mounted transformers. The small transformers provide the consumer with the 120 and 240 VAC needed for house current (at least in the U.S.). When possible, the route is planned to be as direct as possible. The large power lines typically cut across country while smaller lines follow roads and railroads for easier access for construction, maintenance, and to minimize right-of-way costs.

Figure 10: Powerline

A comprehensive study of the entire power system (power grid) provides the input for the actual power transmission line design. Some factors in the study include the size and location of the generators (power plants), the size and location of the loads (the consumers), and the possibility of modifying existing power lines. This information determines the required voltage (and current), the start, and end points of the line. Other influencing factors include soil conditions (soil

Figure 11: Power Transmission Line Network

types, presence of swamps, and presence of corrosive alkali agents), modifications for navigation clearance for rivers and lake crossings, and local climatic conditions affecting line design (yearly temperature ranges, wind velocity ranges, expected ice thickness, and the presence of corrosive sea salts, smoke, or fog).

The operating voltage and current of the line and the environmental concerns determine the type of pylon construction; the size, number, and type of conductors and insulators; and the required clearances (including vertical height of the tower) around the line.

The conductor carrying the electrical current must be able to handle the demands of the circuit. Smaller electrical loads allow the use of smaller conductors. The type of conductor (size and insulation), line voltage, and span lengths dictate the required safety clearance. Every power line has certain minimum clearances dictated by the line voltage. Small shielded cables carrying low voltages can be mounted on short poles. Unshielded conductors carrying high voltages must be placed high above the ground surface. These high voltage conductors have large ceramic insulators, which may be up to one foot in diameter and several feet long. The basic insulator dimension in the U.S. is 146 mm (5 3/4 in) thick by 254 mm or 267 mm (10 in or 10 1/2 in) in diameter. Multiple insulators are linked to protect from shorting and arcing. Smaller voltage circuits only require the small insulators commonly seen on the small distribution poles. The design of the insulators is based on the three major considerations of the 60 Hz voltages: actual power frequency operating voltage, voltage transients from lightning strikes, and those transients caused by switching (switching voltages). These constraints also dictate the height of the transmission tower.

A 3-phase voltage carries the electric current, with one conductor carrying each phase. Therefore, each 3-phase circuit requires three conductors. The size of the conductor is determined by the voltage, conductor surface (solid vs. stranded and construction material such as copper, steel, or aluminum), and altitude (relating to corona loss, power loss, to the atmosphere). Additionally the line must maintain integrity during stress loading by the mechanical forces from line tension, wind, and ice loading. The most economical conductor is steel reinforced aluminum. Conductor size varies from .5 centimeter (for a low voltage line) to more than 2.2 centimeters (for a very high voltage line). A pylon can carry more than

Figure 12: Span Length and Clearances for Medium Load Circuit (U.S.)

Figure 13: U.S. 'H' Pylon Construction

one circuit, two high voltage circuits can be carried or one high and one low voltage circuit. In addition, one or two sets of smaller wires are placed on an extension at the top of the tower to protect against lightning strikes and to form the overhead ground for the circuit. Overhead ground wires run in size from .914 cm (.360 in) to 1.387 cm (.546 in). Low voltage lines often use an earth-contact ground instead of overhead grounds. The spacing of the conductors (distance from conductor to conductor) is also critical. In high wind conditions, closely spaced conductors can gallop (and touch), causing intermittent shorting resulting in actual damage to the line. Additionally electrical equipment using the circuit can also be severely damaged.

Electrical transmission towers (pylons) carry the suspended electrical conductor along the route of the power line. These towers are spaced at regular intervals. The regularly spaced pylons are much easier to detect than conductors. The towers are classed according to three functions.

These functions are tangent, angle, and

Figure 14: Russian 'H' Pylon Construction

345	1.24 (.488)	3.658 (12.0)	9.144 (30)

Figure 15: Conductor and Insulator Size, Medium Load Circuit (U.S.)

tension structures. This refers to the method used to suspend the conductor from the tower. From 80% to 90% of the pylons in a power line are of the tangent class, that is, the conductor is suspended from the tower. The end towers (and often where the line changes directions) of the line are tension type. That is, the tower must be built to accommodate the additional tension (or pull) placed upon the tower since the line is actually affixed to the conductor in a solid connection. Angle towers are also placed under additional stress from the conductor leading off at an angle from the tower. Typically accommodation is through tower guying. The interval between towers varies with tower size and the terrain crossed, ranging from 25 meters to more than 500 meters. Clearcuts within forested areas provide protection against vegetation shorting the conductors. Power pylons are placed clear of buildings and structures.

Local economics and the availability of materials determine the composition and configuration of the pylons. The configuration of the pylon varies, several shapes of pylons are commonly used. Pylon classification is by their resemblance to letter shapes. The pylons are classified according into 'A' type, 'H' type, 'T' type, or 'Y' type. Rarely, other shapes ('V' type for example) can be found.

Figure 16: Tangent

Figure 17: Angle

Figure 18: Tension

Power lines, no matter which pylon type is predominant, usually use 'A' type or reinforced 'H' type pylons at the terminal points (tension) and at turns (angle). Construction materials vary depending on availability and strength requirements. Common materials are wood, concrete, and steel. Steel pylons are in the form of latticework towers or solid poles. Concrete towers are pre-cast material, usually around a solid steel core. Steel and concrete towers are standard heights (within a system). The height of wood towers varies more than steel and concrete towers. Power lines using wooden pylons will have steel towers at turns and terminal points (substations). Wood pylons will have more cross-bracing and guy lines than other types. This provides added structural support.

Figure 2.3: Typical Russian and CIS Pylon Usage

Power Generation

Internal Combustion

Internal combustion power plants provide power for peak load demands. They are used for electric power in isolated areas (without a power grid), base power for industrial plants, or standby (emergency) power for installations. Internal combustion plants use gasoline, diesel, methane gas, or natural gas for fuel. The power output for an internal combustion plant is around 2800 kilowatts per generator unit (for a large gas turbine generating unit).

Figure 24: Generation of Electricity

Figure 25: Components of an Internal Combustion Power Plant

The generators can be housed in a building, or may be open to the weather. Each unit will consist of an internal combustion engine coupled to a generator. The engine will have air intakes, exhausts, and mufflers. Gas (jet) turbines have large intakes and exhausts accommodating the large amounts of air required for operation. Reciprocating engines will have cooling facilities, in the form of radiators or other means, available. Gas turbines require no cooling. Fuel cell power plants (using a entirely different technology from internal combustion plants) look like a very clean small gas turbine plant without any exhaust provisions. This technology is in limited use at present.

Figure 26: Reciprocating Engine Power Plant

Thermal Power Plants and Turbines

All thermal power plants use steam driven turbines, a boilerhouse (equipment to generate heat and steam), and a generator hall. The daily operation of the plant requires large amounts of water. Most thermal power plants are located next to bodies of water. At least minimal water treatment facilities are necessary at the plant.

Figure 27: Gas Turbine Power Plant

High pressure water is injected into the boiler for conversion to high pressure steam. The steam drives the steam turbine, which is connected to the generator by the turbine shaft. The electricity generated is passed to the power plant's transformer yard. There the voltage is stepped up for transmission.

The steam exhausted from the turbine is extracted under a vacuum and sent to condensers for conversion to water. Fifty percent of the heat generated at the power plant is waste heat. The power plant uses one of two systems to dispose of the heat. In the open system, the condenser water is discharged directly to a lake or river (the water is used once and discarded). In the closed system, cooling towers and ponds cool the water for reuse.

Figure 28: Steam Turbogenerator Components

Figure 29: Thermal Power Plant Components

Figure 30: Thermal Power Plant Fuel Sources

Fossil Fuels

Power plants can use coal, oil, natural gas, peat, wood, trash, or a mixture of fossil fuels. These plants have in common the same components and requirements. These are fuel handling equipment, boilers and steam turbines, condenser systems, a feedwater heating system, a system to handle flue gases and wastes, and a control system.

The typical power plant has a 30-180 day fuel supply stockpiled. Rail, barge, pipeline, and/or trucks deliver the fuel. Specialized equipment unloads and stockpiles the fuel. This equipment varies by the delivery method, but includes metering stations (oil and gas), conveyors (transport fuel from unloading to storage areas), coal tipples, and cranes or power shovels. The fuel is stored in tanks, bins, hoppers, or in open storage yards. Coal is stockpiled in large open storage yards. Oil is stored in bermed tank batteries. Power plants fed by natural gas pipelines may not have an on site storage facility. Peat and other low BTU fuels are stockpiled in parallel rows in open storage. Conveyors and pipelines retrieve the fuel, and the fuel is prepared for burning. Conveyors for low BTU fuels are wide and of the open type, compared to the narrow, closed conveyors used for coal. Oil is pumped to a day tank (a one day supply for the boiler) where the oil is heated before injection into the boiler. The oil is atomized immediately before injection to increase fuel efficiency. Coal is pulverized at the storage yard and sent by pneumatic conveyors into the plant. Gas is piped directly from the pipeline or from adjacent storage tanks. Fossil fuel plants using peat, wood, or trash as primary fuel require more fuel preparation and larger fuel storage areas.

In the plant the boiler burns the fuel to produce the steam needed to run the turbines. The tall boilerhouse is often attached to the smaller generator hall. Feedwater heating equipment preheats the water before use in the

Figure 31: Coal Thermal Power Plant

Figure 32: Gas Thermal Power Plant

Figure 33: Oil Thermal Power Plant

Figure 34: Peat Thermal Power Plant

boiler. After the steam passes through the turbine, it is condensed (condenser located under most boilers) and cooled for re-use.

Electrostatic precipitators treat the exhaust gases from the boilers to remove particulates. Scrubbers remove sulfur dioxide and nitrogen oxides. The waste gases are discharged through tall smokestacks. Ash handling equipment removes the ash (cinders) from the boilerhouse for disposal.

Figure 35: Oil TPP Components

Figure 36: Coal TPP Components

Figure 37: Nuclear Fuel Cycles

The control room at the plant can be a separate building, or it can be contained within the boilerhouse and generator hall buildings.

Nuclear

Nuclear power plants use a fission pile (nuclear reactor) to produce the heat needed to run the steam turbines (reactor replaces the boilerhouse). Nuclear power reactors use uranium, plutonium, or a uranium-plutonium oxide mixture (MOX) for fuel. Three basic types of fuel cycles are common. One type uses uranium in a once through operation in the reactor. Then the fuel is discarded. A MOX facility uses an oxide mix of plutonium and uranium. The fuel can be re-processed. The fast breeder reactor during power production concurrently produces an excess of plutonium. The plutonium is then processed into more fuel. The reactor configuration varies greatly. There are numerous reactor designs for different fuels and using various heat transfer and cooling schemes.

Figure 38: Containment Vessel Profiles

Figure 39: Pressurized Water Reactor (PWR) Power Facility

The shield building covers the reactor's primary containment structure. This is the largest and tallest building in the complex. Thermal energy is circulated from the primary cooling system to a secondary cooling loop in one scheme, the pressurized water reactor. The generator hall can be attached to the shield structure or can be a separate building. Another auxiliary building, attached to the shield building, handles the fuel rods and houses the reactor controls.

Waste heat and the electricity produced are handled the same as other power plants. A major problem with nuclear power plants is the handling and disposal of the fuel rods, which are highly radioactive after use. One quarter of the fuel rods is replaced yearly. Once fuel rods are removed from the reactor through the

Figure 40: PWR Containment Building

Figure 41: PWR Steam Generation

auxiliary building, they are stored in pools (situated next to the reactor, with high load overhead cranes) and eventually shipped for reprocessing or disposal.

Another waste produced is the waste gases vented from the reactor. To minimize exposure to these gases, they are vented through a waste gas stack, usually an extremely tall stack next to the reactor. The stack also vents gases during emergency reactor excursion.

Figure 42: PWR Generator Building

Figure 43: Nuclear Plant Components

Nuclear power plants have heavy security with at least one row of security fencing around the area. A nuclear power plant is identified by its neat and clean appearance and the containment facility. Reactor facilities in most countries use an environmental containment structure. This structure isolates the reactor vessel and any produced gases and radiation leakage from the outside. Some reactor facilities, most notably in Russia and the CIS, use a bio-hazard type contain-

ment facility. These structures isolate the nuclear material only during normal operation. Any breach of the reactor vessel (core melt-down, explosion, or coolant loss) will result in leakage into the atmosphere. Reactors without a transformer yard (or a small yard) are not being used for power generation. Such reactors are used for research or production of the special nuclear material (SNM) used in weapons production.

Figure 44: Nuclear Power Plants

Figure 45: Geothermal Well Components

Geothermal

Geothermal plants use heat derived from subsurface waters as a heat source. Wells bring the geothermally heated water to the surface. Heat transfer loops extract the heat for use in the turbogenerator. There are three types of geothermal plants. In hydrothermal plants, hot subsurface rocks heat water and a well extracts this heated water for use at the plant. Hot pressurized water runs geopressured plants. In a petrochemical plant, wells inject cool surface waters into

Figure 46: Hydrothermal Power Plant

the ground, hot subsurface rocks heat the water, and the extracted water runs the turbines.

Other

Solar energy can be directly used to heat water for a power plant. A series of mirrors concentrates the sun's rays on a central tower, water (or a suitable material) is heated, and the heat is transferred to steam turbines connected to generators. Another method uses fields of solar concentrators, mirrored troughs containing pipes, which absorb the heat for transfer to the turbogenerators.

Direct conversion of solar energy to electricity is used in small scale, isolated electricity production. A series of photocells produces electricity that is immediately used or stored in arrays of batteries.

Another method of generating electricity is the magnetohydrodynamic generator. This is a method using thermally ionized gas (passed through a duct under high temperature, pressure, and velocity) **directly** generating electricity. The duct is contained within a transverse magnetic field. The induced magnetic field produced is tapped by electrodes placed within the ductwork. Heat to operate the generator is produced from nuclear

Figure 47: Solar Electric Cells

Figure 48: Solar Collector Tower Power Plant

Figure 49: Trough Concentrator Power Plant

reactors or fossil fuels. This system has the advantages of no moving parts, high efficiency (greater than 85%), and the waste heat may be used to power a secondary conventional thermal power plant.

Prototype plants are operating on a small scale. Since this type of plant requires about 15% of the power output to sustain the magnetic field, the magnetohydrodynamic plant is suitable for a base load plant only.

Hydroelectric

Hydroelectric plants use the hydraulic head (water under pressure) to turn turbogenerators and produce electricity. The plant requires a dam (to impound and store water), waterways (to transport water), and turbogenerators (hydraulic turbines running generators).

Hydroelectric plants are classified by the extent of the impound (storage, pumped storage, or run-of-river plants), the plant's intended usage (peak load, base load, or isolated plant), or the type of hydraulic head used (high head of 150 meters or greater, low head of less than 15 meters, and medium head between the two extremes). Plants are also classified by the relation of the impound water to the generators. A separated plant's dam is at a different location from the generators. The consolidated plant has collocated generators and dam. The construction of the dam depends on the topography of the site, the character and extent of the drainage area, the expected flow variation, and the purpose of the dam. High dams are dams with a height exceeding 30 meters. Low dams are those with a height under 30 meters. The height of the dam does not necessarily correspond to the head produced. Run-of-river dams are constructed to take advantage of 30% to 40% of the expected maximum flow.

Figure 50: Consolidated Hydroelectric Power Plants

Figure 51: Separated Hydroelectric Power Plant

Figure 52: Run-Of-River Low Dam Hydroelectric Power Plant

Figure 53: High Dam Storage Hydroelectric Power Plant

Figure 54: High Head Pumped Storage Power Plant

Figure 55: Penstock Cross-Sectional View

Figure 56: Penstock and Power Plant

A storage dam impounds larger amounts of water behind the dam to use 50% to 75% of the expected flow. Pumped storage facilities pump water uphill to an impound basin and dam for use during peak demand.

The waterways linking the dam to the turbines can be in the form of tunnels, open canals, flumes, or enclosed penstocks. Water enters the waterway through intake towers that also control the water flow.

A penstock is a large pipe originating at the water source and terminating at the turbine. Changes in flow rate and pressure can cause damaging shock waves within the pipe. Surge tanks are located at the midpoint of the penstock to protect from hydraulic jump and to provide constant flow to the generators. Large concrete anchor blocks are spaced along the penstock. The water from the penstock drives the turbines in the powerhouse. The pure velocity of the water drives impulse turbines (Pelton Wheel). A mixture of pressure and pressure converted to velocity drives reaction turbines (Francis turbine and propeller turbine). The used water is exhausted back to the watercourse through draft tubes (pulling water out under vacuum, increasing turbine efficiency and converting the velocity head back to a pressure head), tailraces, or tunnels.

Figure 57: Draft Tube and Reaction Turbine

The turbogenerators can be contained within a building at the dam, placed on top of the dam, or contained within the dam structure. The power output of the turbogenerator is a function of the volume of flow and the hydraulic head available for use ($P \text{ (kW)} = Qh/k$, where Q is the volume of flow in cubic feet per second, h is the height water falls in feet, and the constant k is 11.8, a dimensionless number).

Figure 58: Powerhouse and Impulse Turbine

Tidal plants operate exactly as any other hydroelectric plant. The tidal plant has its dam placed across a bay or estuary, usually in an area with large tidal variation, and the difference in tidal levels runs the turbines. Most tidal plants have bi-directional turbines (turbines operate in either direction).

Figure 59: Tidal Hydroelectric Power Plant

Wind

Most wind power generators produce electricity at a small scale in isolated locations. Some large scale generating plants are operational. Power output for a single large aerogenerator (with a rotor diameter of 120 meters) can be 3.5 megawatts. These plants use fields of wind turbines (numbering in the hundreds) to generate large amounts of electricity. Aeroturbogenerators use a wind powered blade coupled directly to the generator. The wind generator has a bulbous housing around the turbogenerator. An aerogenerator lacks the mechanical coupling necessary to operate a pump, differentiating the aerogenerator from a windmill used to pump water.

Figure 60: Aeroturbogenerators

Heat and Steam Plants

Some plants provide only heat (in the form of steam) for district heating purposes or for industrial processes. These plants normally use oil or coal for fuel. A steam plant has no transformer yard. These plants are centrally located in urban areas, or are associated with manufacturing. The plant consists of fuel storage (not as much storage as a power plant), fuel handling equipment, a boilerhouse

Figure 61: Steam Plant at Sugar Processing Plant

with smokestack, and numerous steam pipes. Steam pipes have heavy insulation and frequent expansion joints. The pipes are sometimes suspended clear of the ground surface. Some systems only have a feed line with no return line (the condensate discharges into the sewer).

Processing

Water

The sources of water are reservoirs, lakes, streams, and wells. Some water sources such as wells, upland lakes, and stream headwaters are fairly clean and non-polluted. Other sources such as the middle and lower reaches of rivers and reservoirs usually require treatment because of pollution and sediments (turbidity) in the water. Even rain water collects impurities from the atmosphere in the form of dust and gases. Water entering the supply system carries pollutants ranging in size from very coarse (leaves, wood, and fish) to very fine. Pollutants can be in suspension (rock and organic debris), in colloids (clay particles and living organisms), and in solution (minerals and gases). Some pollutants only cause unpleasant tastes and texture, while others cause disease or toxic effects. The result of water treatment is an assured supply of safe water in ample amounts

Collection

Main sources of water are unprotected surface waters (streams, rivers, and lakes), protected surface waters (reservoirs and lakes with no polluting activities allowed within the watershed), and sub-surface waters (wells).

Collection of surface waters (lakes, streams, and reservoirs) is from intakes. The intakes withdraw water from the least polluted level of the water source.

Different levels beneath the surface have varying amounts of sediment, debris, and organic contaminants. The

intake can be a simple pipe extending into the middle of the stream, a complex of intake towers, or vertical piping with adjustable gates at various levels. Coarse screens to remove large objects and a series of finer screens to remove smaller objects cap the intake pipe. Cribbs are intakes protected by timber works set in rock at the

Figure 6.2: Solar Heating Panels

Figure 1.1: Intake Tower

Figure 1.2: Intake Crib

end of the intake pipe. Reservoirs use intake towers either placed in the middle of the impound or attached to the face of the dam structure. Canals divert water to intake ponds in some instances. Overflow dams impound water in rivers with erratic and low flow. Another method of intake involves the use of infiltration galleries. Infiltration galleries extend either from the shoreline into the stream (below the surface) or they extend along the shoreline. They consist of a series of perforated pipes surrounded by gravel and sand.

Access to sub-surface waters is by drilled or dug wells or by tapping natural springs. Wells have pipes leading from the wellhead to a pumping station or central collection point for water treatment.

Storage

The water supply must have sufficient storage capacity to meet the system needs. Storage is available for untreated water (to compensate for periods of low water flow) and treated water (to counter interruptions in the distribution systems). Raw water storage is in the form of storage reservoirs, lakes, and catchment basins. Water systems using large rivers (sufficient flow assured) and lakes will not need a large amount of raw water storage.

Figure 1.3: Infiltration Gallery

Treatment

Water treatment destroys disease causing biological agents, eliminates organic matter affecting taste and odor, and eliminates harmful chemicals. The treatment involves a sequence of mechanical and chemical processes. Mechanical cleaning is by a series of coarse and fine screens to remove large particulate matter. Desedimentation basins remove suspended material. Chemical purification removes and neutralizes bacteria and fine organic materials. Flocculation removes colloidal substances and precipitation removes dissolved chemical material. Final treatment is the addition of chemicals to maintain water quality during transportation and to reduce the corrosiveness of the water.

Potable water treatment consists of mixing with coagulants (various sulfate compounds) to force aggregation and flocculation of suspended organic materials. Clarification tanks separate the flocculated solids from liquids. Diatomaceous earth or sand filters remove any remaining solids. Treatment with ozone or chlorine disinfects the water. Additional treatment by softening agents, activated carbon filters, and aeration equipment completes the cycle.

The actual facilities at a water treatment plant vary depending upon the water source. Water from polluted sources requires complete treatment systems. Water from relatively clean sources requires minimal treatment. Water solely intended

Figure 1.4: Water Treatment Components and Processes

for industrial use doesn't require complete treatment. All treatment consists (to some extent) of sedimentation, coagulation, flocculation, clarification, and filtration. The age of the facility determines the equipment configuration. Modern plants combine several operations in one equipment structure, i.e., multiple operations such as mixing and settling occur in the same location rather than at separate locations.

Presedimentation Treatment for water from a highly polluted and turbid water source begins with presedimentation basins. Presedimentation basins are large open rectangular or circular structures a few feet tall. The water sets for 4 to 8 hours, allowing suspended clay, sand, and heavy solids to settle to the bottom of the vessel. Continuously operating sludge collectors remove debris from the basin. Basins without sludge collectors use multiple parallel presedimentation basins. This allows the operation of some basins during cleaning of the others.

Figure 1.5: Presedimentation Basin

Rapid Mixing Water free of gross suspended and heavy solids still contains micro-organisms, colloidal materials, and dissolved substances. The removal of these substances is the aim of the purification and softening processes. Rapid mixing, flocculation, clarification, filtration, aeration, and sedimentation are the steps involved in purification and softening. The first step is rapid mixing.

Water mixes with chemicals in rapid mixing basins. This mixing causes the fine impurities to coagulate (forming flocs). Alum is the coagulant chemical. Lime and soda ash cause the flocs to precipitate out of the solution. The rapid mixing

Figure 1.6: Rapid Mixing Building, Flocculation Basin, and Clarification Basin

(addition of the chemicals) occurs either on the suction side of the operating pumps or in a separate small mixing tank. The separate tanks are small, open, circular or rectangular concrete structures. Often the tanks are next to the flocculation basins. Otherwise the tanks are within the tall multistory chemical tower (containing the gravity fed chemical storage tanks) associated with the chemical treatment building.

Flocculation Basins After rapid mixing, the mix flows into flocculation (settling basins) where the mixture has time to entrap additional material. The flocs grow in size while paddles stir the water. The slow mixing allows added softening chemicals additional time to react. The flocculation basins are large (usually open) rectangular tanks (circular tanks are possible). Most tanks are concrete, although steel construction is possible. The flocculation basins are between the rapid mixing basins and the clarification basins.

Clarification Basins The water and floc mixture flow into clarification basins. The mixture settles for 2 to 6 hours. This allows sufficient time for the floc to settle. The clarification basins are two to four times larger than the flocculation basins. Two types of clarification basins exist. One type is a simple large open rectangular basin with a baffle. The baffle extends three quarters of the way across the basin. Built in pairs, one is in operation while the other is undergoing sludge removal.

The second type of clarification basin uses mechanical scrapers to remove the settled flocs. Scraper equipped basins are circular or rectangular concrete tanks. Often the flocculation basin is attached directly to the end of the tank.

Figure 1.7: Clarification Basin With Scrapers

Filters Filtration systems are the primary processing operation in water treatment. Filtering units remove the very fine floc particles and any suspended colloidal material (such as bacteria) which did not settle in the clarification basin. The two types of filtration systems are the rapid sand filter and the slow sand filter.

Large modern treatment plants use rapid sand filtering systems. Water will be pretreated by sedimentation or clarification basins before filtration. Gravity type rapid sand filtration systems consist of a series of 6 meter square (20 feet square) rectangular basins. The basins contain layers of sand (70 cm thick), gravel, coarse stone, and a mix of coagulant chemicals (fixed to the sand), all over an underdrain substrate system. Water passes through the filter at the rate of 100 to 250 million gallons

per acre (of filter) per day. Floc entrapment in the gelatinous coating and in the interstices of the sand filters the water. The clean water passes into the underdrain system and on to the clearwater basins for storage. The vast amount of water would soon clog the filter, so frequent cleaning is a requirement. Back flowing (backwashing) clean water through the sand cleans the rapid sand filters. The backwash water flow direction is reverse to the operational flow direction. The reverse flow carries entrapped debris out of the filter for disposal. Elevated water tanks store the clear water used in the back flow operation. A long narrow building often houses the entire filter system.

Pressure type rapid sand filters are horizontal or vertical tanks (enclosed) containing the sand and chemicals. Pumps force the water, under pressure, through the sand. The treatment rate is 250 million gallons per day for a tank of 2.5 by 4 meters (8 by 14 feet).

Figure 1.8: Rapid Sand Filter Cross-Section

Figure 1.9: Rapid Sand Filter Building

Photo Interpretation Training Course

Slow sand filters operate on the same principle as rapid sand filters. However, the water filters through thicker layers of sand. Because of the reduced flow, there will be more acreage of slow sand filters to filter an equivalent amount of water. Slow sand filters consist of a series of quarter acre open basins, 62 by 15 meters (205 by 50 feet) in size, and 1.8 to 3 meters (6 to 10 feet) in depth. In cold climates a roof and an earthen berm cover the slow sand filter. Manholes provide access to the filters below. The slow sand filter consists of sand (120 cm thick) over a gravel substrate through which water passes to collector basins below. Clean sand (stored in sand towers located on the sides of the filter) replaces dirty sand when required. Slow sand filters are common in Asia, Africa, and Eastern European countries. Water that has already undergone sedimentation filtration and chemical treatment filters at a rate of 10 million gallons per acre per day (1 acre = 43,560 ft², 1 hectare = 10,000 m², 1 acre = .4047 hectare). Turbid river water without presedimentation filters at 3 million gallons per acre per day. Clear river water filters at 4 to 6 million gallons per acre per day. Lake water filters at 8 million gallons per acre per day.

Rarely, roughing filters treat water from the presedimentation basins. These filters are small units, resembling slow sand filters, removing large particulate matter. Roughing sand filters prevent overloading of the slow sand filter.

Figure 1.10: Slow Sand Filter Cross-Section

Figure 1.11: Slow Sand and Roughing Filters

Multiple Purpose Purification

Units Multiple purpose purification units are pieces of equipment performing multiple functions within one unit. The unit treats the water by flocculation, clarification, and rapid sand filtering. Usual deployment is in groups of four to six purification units and a washwater storage tank. The multiple purpose unit is a small, compact, circular concrete or steel tank. The principle of operation is the same as separate basins.

Figure 1.12 Multiple Purpose Purification Unit

Aerators and Sedimentation

Basins Aerators remove objectionable odors, flavors, iron, and manganese from the purified water. Taste and flavor improve from mixing with oxygen. Release of carbon dioxide allows the iron and manganese to fall out of solution. Most aerators are a grid system of pipes equipped with spray nozzles. The nozzles spray

Figure 1.13: Purification Unit Operation

Figure 1.14: Multiple Purpose Mixing, Flocculation, and Clarification Unit

the water (up to 30 feet into the air), aerating the water. River water usually does not require aeration.

The precipitated iron and manganese settle out of solution in small rectangular sedimentation basins (tanks) sited near (or under) the aerators.

Disinfection The final step in water treatment is disinfection. Chlorine, ozone, and other chemicals added to the water eliminate any surviving bacteria. Fluoride is another chemical added at this time. One of the treatment plant buildings contains these small pieces of equipment. Storage tanks hold the chlorine solution.

Figure 1.15: Aerators

Figure 1.16: Modern Water (Quality) Treatment Plant

Figure 1.17: Water Treatment Plant Schematic

Storage Clean water storage is in reservoirs, water tanks, and standpipes. Pure-water storage is at the treatment plant. Additional storage locations are throughout the distribution system. Most reservoirs of clean water are covered, rectangular or circular, earth-bermed basins. Water towers provide both water storage and the capacity to maintain pressure (in the case of pump failure) in the distribution system. A water tower is a cylindrical or spherical tank on top of a steel or wood supporting framework. Standpipes provide limited storage and a pressure backup capacity. Standpipes are vertical cylindrical steel or concrete towers.

Desalination

Processing in desalination plants produces water for industrial and residential use. Desalination is a very expensive process. The location of most desalination plants is

Figure 1.18: Water Towers

Figure 1.19: Water Tanks

Figure 1.20: Standpipe and Clearwater Reservoir

in coastal areas that do not have an adequate fresh water supply. An additional requirement is a source for the large amount of electrical energy necessary for the operation of the desalination equipment. Most desalination plants use multiple stages of evaporation and condensation in the distillation process. A typical multistage flash distillation plant produces over 7.5 million gallons per day of potable water. Electrodialysis produces potable water from brackish water. Semi-permeable membranes produce water in the reverse osmosis system. A disadvantage for this system is the requirements for high pressure equipment. The hydrate chemical processing, direct freezing and vapor compression (very high cost), and ion exchange columns are also systems producing potable water.

Transportation

Aqueducts are the pipelines, canals, and tunnels transporting water. Aqueducts transport water from the intake facility to the treatment plant and from the treatment facility to the storage and distribution points. Aqueducts can be open as in

Figure 1.21: Multistage Flash Distillation Desalination Operation

canals or closed as in pipelines and tunnels. The water flows under the force of gravity or under pump pressure.

Distribution

The water distribution system is the complex of distribution reservoirs (water tanks, water towers, and standpipes), water mains (arterial, feeder, and street), pumping stations, and valve systems. The distribution system delivers water to the user and assures minimal disruption to the flow. Several service areas make up a large water system. Each service area has its system of reservoirs, tanks, and pumping stations. The separate distribution reservoirs insure a temporary supply of water in case of shutdown due to repair, maintenance, or emergency. The water mains form the distribution lines for the system.

Deep burial protects the water lines from freezing or damage. The water mains are most often buried under the streets. The usual patterns are dendritic, grid, or belt. In the dendritic pattern, arterial mains are along main roads. Feeder lines branch off along secondary roads. Street mains, off the feeder lines, connect to service lines to individual consumers. The grid pattern has an interconnecting pattern of arterial, feeder, and street mains. Proper valve placement assures no interruption to service will occur. The grid pattern is commonly found in the central sections of large cities. One great advantage to the grid system is the ability to maintain high flow rates and water pressure, useful during fire-fighting. The belt system forms a ring of arterial and feeder mains around the city. The street and service mains branch off the main loop and dead-end at the consumer.

Arterial mains are usually concrete and have a diameter of 1.2 meters (48 inches), 1.5 meters (60 inches), or 1.8 meters (72 inches). The concrete, cast iron, or steel pipe feeder mains are from 0.6 to 0.8 meters (24 to 30 inches) in diameter. The cast iron and steel street mains range from 0.3 to 0.6 meters (12 to 24 inches) in diameter. The size of the service connection (pipe connecting the street main to the consumer plumbing) varies, but are normally only a few centimeters in diameter. Mains are buried from 0.6 to 2.1 meters (2 to 7 feet) beneath the surface. Every interconnection point and change in pipe size along the distribution system has at least one valve. The number of valves throughout a typical system is in the tens of thousands.

Ferrous Metals

Steel (the generic term for ferrous metals) production is ten times greater than the combined production of all other metals. Virtually all construction, manufacturing, and transportation industries require steel.

Ferrous metals consist of pure iron (ingots and wrought), cast iron (iron and 2% to 5% carbon), steel (iron with less than 2% carbon), and alloy steel (iron,

Figure 1.22: Aqueduct Crossing Stream

Figure 2.1: Integrated Coke, Iron, and Steel Plant

carbon, and additional alloying elements). The production of ferrous metals is in large complexes consisting of coke plants, iron production plants, steel plants, and steel forming and finishing plants. Steel production requires considerable plant integration to minimize the cost. Integrated plants will possess all the facilities to take raw ores and produce the finished steel product (coke plants, iron plants, steel production, and rolling and blooming mills). Semi-integrated plants have steel plants and the rolling and blooming mill complexes. Non-integrated plants have a few components of the process.

Coke

Coal supplies 65% of the energy requirements of steel production. Almost all (95%) of the coal goes into the production of coke. Coke is the distillation of bituminous coal into a solid carbon product. The coke forms the fuel for blast furnaces, which require 454 kilograms (1000 pounds) of coke per 1000 kilograms (1 ton) of pig iron production. The coke, in the form of carbon monoxide,

produces a reducing atmosphere in the furnace. This prevents oxidation of the iron. The coke provides a porous bed in the furnace for the iron ore charge. Blast furnace operations use 90% of the coke produced; foundry operations use 4%; 1% goes toward water gas production; and carbide, nonferrous metals, and phosphate production use the rest.

The preparation of coke from bituminous coals is by dry distillation (pyrolysis). As heating proceeds from 100° C. to 510° C. (220° F. to 600° F.); water, hydrocarbon gases (methane, carbon monoxide, and hydrogen), hydrogen sulfide, and hydrocarbons (light oils) evolve from the coal. Above 400° C. (750° F.) the framework of the coal breaks down and the mass becomes plastic. The escape of the volatile components leaves a porous structure of coke behind. The final temperature of the coke determines both the residual volatiles and the ignition temperature. Coke heated to 538° C. (1000° F.) forms low temperature coke (for the manufacture of city gas). Coke heated to 1000° C. (1850° F.) forms a high temperature (metallurgical grade) product. Not all coal is suited for coking. Coal high in sulfur, low ash melting point, and friable coals are not suitable for coke production.

Coal Preparation

Coal arrives at the coke plant in railcars, ships, and barges. Car dumpers unload the railcars and clamshell buckets unload ships and barges. Conveyors transfer the coal from the unloading area to a storage area (normally a 60 day supply for the plant). Most coke plants have a coal preparation area between the coal storage and the coke plant proper.

Breakers reduce the size of the coal to 2.5 centimeters (1 inch) and remove foreign material. The hammer mill accepts the pulverized coal and reduces it to a fineness of 80%, or a diameter of .318 centimeters (.125 inch).

Two methods remove mineral impurities from the coal. Froth flotation removes impurities from fine coal. Coal, mixed with chemicals, separates from impurities under the action of bubbled air. Coal, attached to froth, rises to the surface and skimmers remove the coal. The Heavy-Medium Cyclone method removes impurities from crushed coal. Coal, mixed with water and magnetite, separates from its impurities in a tilted cone. The heavy impurities, attracted to the magnetite, exit the bottom of the cyclone. The lighter coal exits the top of the cyclone cone. Dryers remove water from the coal after both processes.

Next, conveyors transport the coal to charging bins located above the ovens. The bins hold a one day supply of coal. Hoppers within the charging bin hold enough coal to fill one charging car (lorry car).

Beehive Coking

An older method of coking is the beehive coking method. Beehive coking produces very high quality coke (high metallurgical quality), but this method is not as economical as the by-product method. Most beehive coking operations are in

Figure 2.2: Coal Preparation

343

Figure 1.7: Clarification Basin With Scrapers

Photo Interpretation Training Course

Chapter 4

344 Cultural Features

Figure 2.3: Beehive Coke Production Flow

underdeveloped countries. A plant shut-down (and oven cool-down) does not damage the beehive plant. Many plants worldwide have been deactivated until again needed (peak production in wartime or for high grade coke production). The location of the beehive plant is close to the coal source (bituminous coal mine), making the plant competitive with by-products coke.

The beehive coke ovens are hemispherical structures built in individual units or oven batteries. The domed shape is not visible since the area around the oven is built up, allowing passage of charge cars. A charge port situated at the top of the oven allows the unloading of coal into the brick or stone lined horizontal oven. Heat retained in the oven from the previous charge begins the distillation process. The released volatiles burn in the space above the charge. Heating continues for 48 to 72 hours. Waste gas and smoke pass out through the charging ports. This provides sufficient heat to drive off remaining volatiles and completes the carbonizing process. Removal of the finished coke is through side doors or through the charging port. Modern plants remove the coke with a ram (mounted on rails). Water quenches the coke (the coke burns upon exposure to air) before screening and sizing.

Figure 2.4: Beehive Coke Production with Machine Charging and Discharging

Photo Interpretation Training Course

Figure 2.5: *Beehive Coke Production with Manual Charging and Discharging*

By-Products Coking

By products coking involves the production of coke and the recovery and use of the by products generated by the coking process. The by-products, in the form of vapors, produce chemicals, plastics, and explosives. The resale of the by products defrays some of the production expenses. The associated industries use the coal gas produced from the coking process. By-products coking is cheaper than beehive coking, but produces a lower quality product.

Two major areas in the by-products plant are the coke oven batteries and the by products area. The coke oven battery is a long, thin, very dark rectangular structure with adjacent coal stockpiles, coal preparation area, and conveyor systems. The by products area is collocated with the coke oven battery. The by products area has many storage tanks and an extensive piping network.

The coke oven chamber is 12 meters long, 6 meters high, and .4 to 1 meter wide (10 feet long, 20 feet high, and 17 to 36 inches wide). The tongue and groove silica brick lining has a taper of 8 centimeters (3 inches) to facilitate the ram operation during coke removal. Self-sealing doors form the ends of the oven. The oven has three or more charging ports on the top. Short vertical (standpipes) pipes on the top or ends connect the oven to horizontal manifolds (mains) that collect the by-product vapors and transport the gases to the by-products reclamation area. A central cooling tower links pairs of coke oven batteries. The cooling tower is a tall rectangular structure centrally mounted on the top of a pair of coke oven batteries. A conveyor links the cooling tower to the coal preparation area. A long line links several pairs of batteries. A coke plant has more than 160 ovens.

Figure 2.6: By-Products Coke Production Flow

Figure 2.7: By-Products Coke Plant

Figure 2.8: Coke Oven Battery Components

A charging car, with 18,000 kilograms (20 tons) of coal per charge, dumps the coal into the oven. A bar on the pusher machine levels the coal charge. The pusher machine is a rail mounted apparatus moving along the side of the oven battery. The machine moves along the pusher side of the oven. The machine has a door extractor for removal of the pusher side door, a leveling bar, and a ram for pushing the red hot coke out of the oven. Leveling provides sufficient gas space in the charge. Excess coal returns to a hopper on the pusher machine.

Burning chambers (flues), supplied with fuel from a dry gasometer, surround each oven. Burning fuel gas heats and carbonizes the coal (destructive distillation). Hot waste gases circulate through regenerators, located beneath the coking chambers, and the retained heat in the checkerwork preheats incoming fuel gas. Waste gas from the combustion vent to the tall waste gas stacks at the plant. Heating of the coal continues for approximately 18 hours. During this time 25% of the coal converts to volatile materials. The ascension pipes and crossover mains collect the gases and transport them to the by-products area. The ovens are kept at operational temperatures throughout the life of the oven. Cooling destroys the oven lining.

The pusher machine (or ram car) removes (pushing with a hydraulic ram) the finished coke from the coke oven. A door machine and a coke guide travel on tracks (on the coke side of the battery). After removal of the coke side door, the coke guide allows the coke to fall into the quenching car (another rail guided vehicle). The quenching car transfers the hot coke to the quenching station. The

Figure 2.9: Coke Oven Battery

Figure 2.10: By-Products Coke Oven Area

quenching station (quenching tower) is a fairly tall rectangular structure (with an open or stack vented top) located at the end of the battery. The quenching station showers the coke with several thousand liters of water. The partially cooled coke continues to the cooling wharf. At the cooling wharf (a flat sloping structure) several charges of coke, spread in thin layers, cool. The cool coke moves

Figure 2.11: Environmental Modifications to By-Products Plant

by conveyor to the separating and screening station for sorting. Vibrators and shakers separate and sort the coke before use. Conveyors or rail cars transport the finished coke to the blast furnace.

Modifications made to coke by-products plant reduce harmful emissions and pollutants.

Coal Chemical Recovery

The by-products area looks like a small petroleum refinery. The area has numerous tanks, columns, and a network of pipes.

The volatile and gaseous by-products from the carbonization process include: tar, light oils, and ammonia. Recovery processes for these substances include: cooling, condensation, scrubbing, and electrostatic precipitation. The recovered tar is a component of many industrial products. Refining of the light oil component yields benzene, toluene, and zylene. Ammonia processing yields ammonia gas and ammonium sulfate (commercial fertilizer components). The recovered gas is re-used at the coke plant or used in furnaces at the steel plant.

Collection of the volatiles generated during the coking process begins as the gases rise through the chamber into the ascension pipes. The gases pass to collection mains, which extend the length of the battery. Liquid ammonia, sprayed into the gases at the pipe junction, condense some of the ammonia and tar. The condensed liquids flow into decantation tanks for recovery. Large crossover mains (larger piping) connect the collection mains from the batteries to the by-products recovery plant.

First the gases pass through primary coolers and condensers that extract the ammonia and tar. The next section is the by-products building. Here, exhausters maintain a partial vacuum on the mains and force the gases into a tar extractor. Changes in the gas flow direction remove any remaining tar. Instead of tar extractors, Cottrell electrostatic precipitators can remove the remaining tar.

Acid saturators receive the gas from the condenser and the ammonia liquor from the decanting tanks. A sulfuric acid reaction converts the ammonia to ammonium sulfate. Fertilizer and explosive manufacturers use the dried crystalline ammonium sulfate.

Figure 2.12: Coke By-Products Recovery Plant

Cooling towers cool the gases from the saturators. Benzol scrubbers spray the cooled gas with heavy wash oil. Strippers vaporize and separate the light oils (benzol) from the heavy wash oil (the wash oil returns to the scrubbers). Scrubbers remove sulfur from the gas, making it suitable for fuel usage. Large gasholders store the gas until ready for use or sale. Fractionating towers separate benzene, toluene, xylene, and naphtha from the condensed benzol. Additional refining yields standard commercial grades of these chemicals.

Pipe furnaces heat the tar from the mains, coolers, and tar separators. Fractionating towers flash the tar and separate pitch, heavy anthracene oils, creosote oils, and light oils. Middle oils (creosote oils) cool in shallow pans, yielding crystalline naphthalene. Centrifuges process the crystalline naphthalene. Wash tanks treat the crystalline naphthalene and liquid naphtha with caustic soda, yielding salts from the tar acids in aqueous solution. Neutralizer (or carbonating) tanks treat the aqueous salts with carbon dioxide forming tar acids. Sulfuric acid treatment separates the tar acid into a tar acid layer and an aqueous sodium sulfate layer. Another fractionating tower separates excess water from the tar acids and separates crude phenol, cresol, and xylenol from the solution.

The non-aqueous solution yields neutral oils, from which additional purification yields pyridine.

Ore Processing

Concentration increases the percentage of metal in extracted ore. Additional processing allows recovery of the metal from the ore. Reduction, refining, and forming processes produce a usable product from the metal-bearing ore. The presence of a particular sequence of processing often identifies the metal under treatment.

METAL	REDUCTION	REFINING	FORMING
IRON	Blast Furnace Smelting	Reveratory or Electric Furnace	Rolling Mills and Fabrication Uses
COPPER	Smelting- Reveratory, Electric, or Blast Furnaces and Converters	Electrolysis or Heat	Fabrication- Alloying and Electrical Industry
LEAD	Blast Furnace Smelting	Refining Kettles	Fabrication- Building and Construction, Batteries, Ammunition
ZINC	Electrolytic, Retort, or Blast Furnaces	Very Complex	Fabrication- Alloying, Steel Galvanizing
TIN	Smelting- Reveratory, Electric, or Blast Furnaces	Electrolytic or Heat Treatment	Fabrication- Protective Coatings, Alloying, Electrical Industry
NICKEL	Electrolysis, Smelting, and Leaching Complex	Not Required	Fabrication- Alloying, Electroplating
URANIUM	Chemical	Chemical	Reactor Fuel, Weapons
ALUMINUM	Electrolysis	Not Required	Rolling Mill, Fabrication Uses
MAGNESIUM	Electrolytic or Carbothermic (heating in retorts)	Not Required	Limited Rolling and Extruding, Fabrication as Ingots, Alloying
TITANIUM	Leaching or Electrolytic	Electric Arc Furnace	Aerospace Industry, Welding Materials

Figure 2.13: Metal Ore Processing Methods

Iron – Raw materials

Coke, limestone, and iron ore are the raw materials used in iron production. Steel is iron with additional refining to reduce carbon content.

Coal could provide fuel for iron production. The preferred fuel for iron production is coke. Coke has greater compressive strength, porosity, and higher carbon purity than coal.

Limestone serves as a flux in iron production. Limestone also combines with the non-gaseous impurities in the iron ore during smelting. Limestone storage is in large open piles (with a light gray to white tone).

The most abundant and common iron ores are hematite and magnetite. Each particular iron plant (and each ore) has its own set of pre-processing requirements. Beneficiation of iron ores (the processes improving the chemical or physical properties) includes crushing, screening, grinding, screening, classifying, concentrating, and agglomeration. Concentration occurs by flotation and magnetic separation. Sintering and pelletizing are major agglomeration methods. Briquetting and nodulizing are other agglomeration methods.

Undesirable components of iron ores include oxygen, silica, phosphorus, and sulphur. The blast furnace eliminates the excess oxygen and some of the other

Figure 2.14: Steel Production

Figure 2.18: Iron Ore Preparation

356

Figure 2.19: Ore Layering and Preparation Yard

Figure 2.20: Direct Reduction of Iron Ore

Iron Production

After the ore goes through the beneficiation process, the iron oxides are reduced to pure iron. The common reducing agents include carbon, carbon monoxide, and hydrogen or hydrocarbon gases. The common reduction processes are smelting in blast or low-shaft furnaces or electric smelters, direct reduction processes, and melting scrap metal in various furnaces.

Figure 2.21: Flow Diagram of Iron Production

Blast Furnace

The most prevalent method of reduction is the blast furnace. Iron ore and limestone, heated by burning coke, produce molten iron metal. Hot air, pumped through the coke, accelerates the combustion process. The production of one ton of iron requires two tons of iron ore, one ton of coke, one half ton of limestone, and four tons of hot air. Another requirement is cooling water, pumped through the furnace wall, to cool the brick furnace lining (temperature exceeding 1650° C [3000° F]). The blast furnace is large, brick lined, steel vessel of 3-15 meters (10-50 feet) in diameter and 15-100 meters (50-300 feet) in height. A typical blast furnace produces 1800-7300 metric tons (2000-8000 tons) of iron a day.

The iron ore (in suitable form of pellets, briquettes, or sinter), coke (carbon and heat source), and limestone (fluxing material) are charged into the stack of the furnace from hoppers (by the skip hoist). Hot air introduced into the bottom of the furnace (through nozzles called tuyeres) from hot stoves aids in complete combustion of the coke. Blast houses pump cool air into the hot stoves for heating. Additionally, the hot air prevents heat dissipation and creates the overpressure necessary for the blast. A hot stove is a cylindrical structure 5-9 meters (18-30 feet) in diameter and upwards of 50 meters (150 feet) tall. Four hot stoves (one in use while other three buildup charges) feed preheated air to turboblowers. Firebrick lining in the hot stove provides thermal mass (interior temperature in excess of 1000° F). The usual fuel is gas from the coke oven batteries and waste

Figure 2.22: Iron Smelter- Blast Furnace

gases from the blast furnaces. The heated air is piped into the bustle and on to the furnace by way of the bosh (encircling the vessel).

The resulting heat melts the furnace charge and reduces the iron oxides. Carbon from the coke combines with the oxygen impurity in the ore, forming carbon monoxide. The carbon monoxide and other gaseous impurities vent through the downcomer pipe. The charge descends through the furnace and halfway down the limestone melts and combines with the non-gaseous impurities. The impurities form a slag,

Figure 2.23: Hot Stove Configuration

Figure 2.24: Hot Store Operation

Figure 2.25: Blast Furnace Components

float to the surface of the melt, and are tapped from the furnace. The purified iron settles to the bottom of the furnace.

A two level building (casting shed) surrounds the lower portion of the blast furnace. Casting operations occur on the upper level and tracks on the lower level allow movement of rail cars. The blast furnace has two casting holes (notches), the upper casting hole produces slag once a hour. The lower hole produces 100-400 tons of iron every 4-5 hours. The torpedo (bottle) car receives the molten iron (up to 10,000 tons per day) from the hearth for transport to the steelmaking furnaces. Or the iron is cast into small molds (pig iron). The slag car removes slag (from the surface of the melt) to the slag pits. The downcomer carries the carbon monoxide and the waste dust away from the blast furnace. The hot stoves receive the carbon monoxide as additional fuel. The dust catcher and dorr thickener remove and recycle the dust.

Other Iron Production Methods

The low-shaft furnace operation is similar to the operation of the blast furnace. These squat circular or oval structures handle low grade coke and fine ores.

Areas with plentiful, low-cost electric power can use the electric smelter for reduction. Additionally, the electric smelter is able to use low grade coke in the process. The circular or rectangular furnace uses submerged arcs powered by transformers supplying 60 mega-volt amps of current.

Less common reduction methods include the SL/RN process; the HYL process; the Purofer, Mildrex, and Armeo processes; and the Fior and U.S. Steel processes. In the SL/RN process high grade ores (pellets or lumps) and solid anthracite coal reductants are mixed with flux and reduced in rotary kilns. Screens and magnetic

Figure 2.26: Iron Metal Production

separators separate the resulting sponge iron (sponge iron is porous or fine reduced iron). The batch-cyclic HyL process requires four fixed-bed reactors (necessary for continuous operation). Suitable gases provide reductants. The four stage process includes: removal of produced sponge iron and charging the reactor, preheating and treatment with partially used reductant gas from adjacent reactor, the primary

reduction process to produce sponge iron, and cooling the iron with fresh gas. The Purofer, Midrex, and Armco processes use shaft furnaces in a continuous operation. Suitable gases reduce top fed iron ore and pellets. The Fior and U.S. Steel processes use fluid-bed reactors fed with reducing gases.

Direct reduction processes produce highly reduced iron. Usually the iron replaces

Figure 2.27: Casting Shed

Figure 2.28: Torpedo and Slag Cars

scrap steel and iron in additional processing. Kilns, furnaces, and fluid bed reactors using various reductants are suitable in direct reduction applications.

Cupola furnaces melt previously reduced sponge iron, scrap, and pig iron for use in casting at a foundry. The cupola is a type of vertical shaft furnace producing 2-75 tons per hour. The furnace burns coke using forced air supplied by injection. Limestone provides fluxing material.

Once the iron ore is converted into metallic iron, it may be poured and cast as pig iron. If steel is the ultimate product, more processing is required to reduce the carbon content of the iron.

Steel

The major methods for converting liquid iron, pre-reduced sponge iron, and scrap steels to steel are the open hearth process, the Bessemer process, the basic oxygen process, the electric furnace, and the Kaldo and Rotor process. Additional processes produce specialized steels. The type of steel desired determines which method is used in the production process. The Bessemer converter produces high nitrogen and high phosphorus steels. The open hearth process accepts a wide range of iron as raw material and produces steel suitable for drawing. The basic oxygen process requires a substantial outlay for iron oxide recovery equipment due to the tremendous amount of oxides produced during processing. The electric furnace produces all

Figure 2.29: Flowchart for the Steel Industry

types of steel (especially alloy steel production). However, its drawback is the requirement for very high temperature in operation.

Steel is a combination of iron, carbon, and various elements in trace amounts. The trace elements are manganese, phosphorus, sulphur, silicon, and alloying elements. Steelmaking consists of refining molten iron and scrap steel by the removal of undesirable elements (primarily carbon). Then alloying element added to the mixture determine the metallurgical characteristics of the steel. Hot metal cars (or metal in solid ingot form) transfer the molten iron to the steel plant. There one of the four steelmaking methods (Bessemer Converter, Open Hearth Furnace, Basic Oxygen Furnace, or Electric Arc Furnace) converts the iron into molten steel.

The processes have similar concepts, but different applications. The result is the production of molten steel, poured into ingots. The ingot is then stripped and soaked. Further processing produces blooms, billets, and slabs from the ingots. At the rolling mills, blooms produce structural shapes, billets produce bars, and slabs become sheet, strip, and plate steel forms. Additionally, foundries require pig iron in their operation, so steel mills often cast pig iron (merchant iron). The merchant iron casting building is a small building (with inclined conveyors extending from the structure).

Steel Production Processes

Figure 2.30: Steel Production

Figure 2.31: Merchant Iron (Pig Casting) Building

Bessemer Converter

The Bessemer converter produces low quality steel and represents a dated technology. Bessemer converters are large, 3 meter (10 feet) high, pear shaped vessels lined with fire brick. A trunnion mount allows the charging of the vessel with 14-23 metric tons (15-25 tons) of hot metal. Jets of air (blown through bottom orifices) oxidize undesirable elements. The processing (blow) lasts about 15 minutes. The waste heat and gases exhaust through large openings in the roof of the building (large open vents are a critical identification clue to Bessemer converter operation). The open top converter can handle only 5% to 10% scrap steel (due to heat loss). Rotation of the converter allows pouring and casting of the steel into ingot form. An oxygen and carbon dioxide mixture replaces the blown air in the production of high quality low-nitrogen steel.

Figure 116: Bessemer Converter

Figure 2.33: Open Hearth Steel Production

Open Hearth Furnace

The open hearth furnace is an open saucer-shaped floor positioned over the flame. The lining is a refractory lining (fire brick) supported by heavy structural steel. A checkerboard arrangement of firebrick under the hearth allows the flow of heated fuel and air. The fuel burns above the hearth at about 1650° C (3000° F). The hearth is the size of a two story house. Water-cooled oxygen lances allow

Figure 2.34: Open Hearth Furnace Operation

the introduction of gaseous oxygen into the molten steel in some modern open hearth furnaces.

A steel plant usually has several open hearth furnaces within one long building. All the furnaces face in the same direction. Doors on one side permit charging the furnace. Removal of the batch of steel (called a heat, from 270-545 metric tons (300-600 tons) of metal) occurs on the opposite side (and on a lower level of the building). A batch of steel takes 5-8 hours (unless oxygen lances reduce the time).

Basic Oxygen Furnace

The basic oxygen furnace (BOF) produces high grade steel in large amounts. The furnace can produce 225-315 metric tons (250-350 tons) of steel in under an hour. Additional benefits include reduced maintenance costs, longer furnace life, reduced construction cost, and reduced manpower requirements (compared to the open hearth furnace). The large amount of excess heat generated in the process allows the use of up to 30% scrap steel during processing.

Molten iron, poured into the furnace, melts the scrap. An oxygen lance blows pure oxygen across the top of the melt at supersonic velocity. The oxygen burns the carbon and impurities in the iron, converting it to steel. A lime flux, added to the melt, forms a floating layer of slag. After removal of the slag, a ladle taps the steel from the furnace. Alloying materials, added to the steel, produce the desired steel alloy. Steel, poured into molds, forms steel ingots. The BOF produces higher quality steel and less pollution than the open hearth furnace (BOF totally enclosed).

Figure 2.35: BOF Operation Cross-Section

Figure 2.36: BOF Building Cross-Section

The large gas and dust collection pipes extending from the top of the tall BOF building to gas cleaning equipment allow the identification of the BOF plant. The pipes form a "Y" shape across the roof of the structure.

Onsite plants produce the oxygen for the BOF. Railcars and tank trucks may supply smaller plants with oxygen. Gasifiers convert the liquefied stored oxygen to gas form as needed for production.

Several modifications to the BOF process improve the steel quality the furnace produces. One modification of the process (Q-BOP) involves bottom blowing of oxygen and hydrocarbon gases instead of top blowing. The Kaldo process uses a rotating pear-shaped furnace with a water cooled lance blowing oxygen across the charge. Or the lance, inclined at 15°, rotates across the top of the furnace. The carbon monoxide produced burns inside the converter vessel. The stirring action results in a complete combustion of carbon and generates more excess heat. The process produces enough excess heat to allow charging with 40% scrap steel. Another modification, the Rotor process, uses a long cylindrical rotating furnace. Two lances inject oxygen into the furnace. A low-purity oxygen flow burns carbon monoxide (produced during processing) and a high-purity oxygen flow (injected into the bath) refines the charge.

Figure 2.37: Operation of Basic Oxygen Furnace (BOF)

Figure 2.38: Gas and Dust Collection Pipes on BOF Building

Figure 2.39: Electric Arc Furnace Operation

Industries

Cultural Features 371

Electric Arc Furnace

The electric arc furnace consists of a firebrick lined round steel shell. Three graphite electrodes conduct electricity through the contents, heating the furnace. The arcing electricity heats the furnace to 1925° C (3500° F). Raw material can be liquid iron, scrap steel, or pre-reduced pellets.

The lack of open flame allows total enclosure of the furnace. The furnace can operate in oxidizing, reducing, or neutral conditions. This allows the production of high-alloy (tool) steels. A heat produces 45-270 metric tons (50-300 tons) of steel per charge.

Initial Steel Forms

After steel production, casting allows working into the required form. A ladle (refractory lined car for transport of molten metals) taps the liquid metal from the furnace. At this point alloying material and deoxidants mix with the molten steel. Treatment of the molten metals includes vacuum processing to remove hydrogen,

Figure 2.40: Steel Forming and Finishing

oxygen, nitrogen, and nonmetallic elements from the mix. Stirring treatments and heat treatments (for 2-3 weeks) perform the same function. Rolling and finishing mills require a solid form of steel for processing.

Remelting and refining produce special alloy products before production of steel forms. These methods include argon-oxygen decarburization, electrosag refining, vacuum arc remelting, and vacuum induction remelting.

Ingot and Castings

Ladles pour (teem) the molten steel into ingot molds of various sizes and shapes. Stools below the molds allow cooling of the steel. Ingot molds are of cast iron construction. The molds are very large 3 meters by 1 meter (9 feet by 3 feet) for structural shape production and very small for tool steel ingot production.

**Photo Interpretation Training Course**

199

Industries

Cultural Features 373

Extremely large molds, holding several hundred tons, receive molten steel for special applications. Hydraulic presses form these steels into stressed products (such as turbine shafts and machine parts).

In casting-pit operation the molten metal teems from the ladle into single or multiple molds (large scale operations). Direct casting of intricate shapes uses sand molds (on small scale). Compressed air forces molten metal upwards into molds in the pressure-pouring process.

Stripping and Soaking Pits

The ingot mold has a coating, insuring that teemed steel doesn't stick to the mold (spoiling the surface quality or interfering with mold removal). Tongs grip the top of the mold while a plunger holds the ingot steady on the stool. The tongs lift the mold clear of the ingot (where it cools for reuse). Recasting of worn out molds is common.

The removed ingots cool from the outside towards the center. Transfer of the ingots to the soaking pits (by way of ingot cars) occurs while the interior is still molten. Soaking pits are large furnaces (long low buildings with multiple smokestacks). The ingots remain in the pits until they reach a uniform temperature of around 1260° C (2300° F). A special buggy (car) carries the soaked ingot from the soaking pits to the roughing mill (usually located immediately next to the pits).

After casting or pouring, reworking the steel produces a semi-finished form. Additional processing converts the semi-finished form into a usable steel product. After treatment in the soaking pits, roughing mills produce semi-finished forms of steel (blooms, billets, and slabs). The reworking mostly involves mechanical processing, altering the shape and size of the ingots into blooms, billets, and slabs. A bloom is a solid form with a cross-sectional area of around 92 square centimeters (36 square inches). A billet is a solid form longer than a bloom with a smaller cross-section. A slab is wider and flatter than a billet.

Figure 2.42: Ingot Soaking Pits

Blooming, billet, and slab mills (primary mills) form the ingots into the steel forms. The mills operate in a similar manner. For example, a blooming mill rolls a white hot ingot into a bloom shape. A mill forms an ingot 48 by 58 centimeters (19 by 23 inches) in cross-section into a bloom with a cross section of 15 square centimeters (6 square inches) in 5 minutes. Once the bloom forms, shears cut the still hot bloom into the required length. Storage of finished blooms, billets, and slabs is in parallel rows of open storage (cluttered appearance).

Strand Casting

Continuous casting of the steel eliminates the requirement for heavy mill equipment. The finished product of a continuous casting operation is a semi-finished shape (billets, blooms, and slabs). Strand casting (continuous casting) bypasses ingot teeming, stripping, soaking, and rolling to produce the semi-finished steel form. A strand casting machine receives the molten steel metal and converts it into the semi-finished solid product.

A ladle carries the molten steel from the furnace to the top of the strand caster. A removable stopper allows the metal to flow from the ladle into the tundish of the caster. The tundish provides for the even flow of metal (a reservoir for the steel) into the casting machine. After passing through the molds (from the tundish), the

Figure 2.43: Strand Casting Machine

steel cools slightly and passes through a series of rollers and cooling plates. Water jets cool the steel as it forms the required shape. Eventually, torches (at the cutting station) cut the cooled steel in the necessary lengths. A strand caster forms steel at about 3 meters (15 feet) per minute.

Forming Finished Steel Products

Hot forges and rolling mills (secondary mills) convert the semi-finished blooms, billets, and slabs into finished usable steel products. Forging, extrusion, and rolling methods produce the steel product.

Hot Forging

The definition of forging is using compressive force along the lines of metal flow to put the greatest strength where needed. Steel forging involves hammering and pressing. Hydraulic hammers working on hot steel resting on anvils perform hammering. In press forging, hydraulic presses push the heated steel block into the required shape. There are two types of hot forging, the open-die and the closed-die. Open dies forge very large parts. Large presses squeeze steel ingots (up to several hundred tons) between two flat surfaces.

Closed-die forges use steam hammers. A steam hammer strikes sections of steel (cut from semi-finished steel, such as a billet) placed between toolsteel dies. The hot metal flows into the desired shape when struck. A ram (or heavy weight) provides the necessary force in the drop hammer method of closed-die forging. Extrusion processing involves hydraulically operated rams pushing the heated steel through dies to produce wires, bars, or tubular goods.

Hydraulics drive most large forge presses. Mechanically driven presses (rotating flywheels transfer energy by way of mechanical linkage) run medium and small forges. Additional forging methods include upsetting and roll forging. These methods knead the steel into denser structures requiring minimal additional cutting.

Rolling Mills

Rolling mill complexes rework most (90%) of the steel into usable form. The rolling mills reduce the cross sectional area of the steel to produce a variety of shapes (sheets, rails, beams, etc.). The rolling mill complex is a large expanse of long narrow buildings. They are the largest buildings at the steel plant. The buildings often connect at 90°, forming "L" and "T" shapes. A rolling mill is a series of horizontal rollers (rolls), one placed above the other, turning in opposite directions. The heated semi-finished steel, passing through the rollers, becomes longer, thinner, and wider. Additional vertical rollers, placed on the side, limit the amount of horizontal spread. Multiple passes produce the finished product.

Each type of semi-finished steel (bloom, billet, and slab) produces a particular variety of finished products. Rolling mills produce structural shapes from blooms. Structural shapes are rolled flanged sections such as I-beams, H-beams, rails, and

Figure 2.44: Steel Rolling Mill Complex

columns. Bar mills produce bars from billets. Grooved rollers produce bar stock from the heated billets. Bar mills produce a variety of bar and rod shapes. Additional processing produces wire from rod stock. The cold drawing of bars (pulled at room temperature through a die) produces bar stock that is strong, polished, and hard.

Continuous sheet mills roll slabs into sheet steel and strip steel. Strip steel is narrower than sheet and produced to a more exact tolerance. The hot continuous strip mill is several blocks long. The processing produces 1070 meters (3500 feet) per minute of coiled strip steel from a slab 18 centimeters (7 inches) thick. Cold rolling of strip and sheet steel produces a base for coated products (tin plate).

Plate mills produce plates from slabs. Heavy construction (bridge floors and oil tanks) uses plates. A plate is a piece of steel between 15 and 120 centimeters (6 and 48 inches) wide and .6 centimeter (.25 inch) thick, or, more than 122 centimeters (48 inches) wide and more than .5 centimeter (.1875 inch) thick.

The finished steel product cools in long narrow (with vented roofs) cooling warehouses before storage and shipping.

Non-Ferrous Metals

Aluminum

Aluminum production is second only to iron production. The electrolysis of alumina (reduction) in cryolite produces aluminum. The chemical, ceramic, and petroleum industries use alumina. The construction, vehicle, aero-space, electrical, and durable goods industries use aluminum metal.

Alumina

The Bayer Alumina and the Lime Soda Sinter processes produce alumina. The four production steps (both processes) are digestion, clarification, precipitation, and calcination. The Lime Soda Sinter process also has rotary kilns, soda ash and limestone storage, and crushing and leaching areas.

Figure 3.1: Bayer Alumina Plant

Pre-drying bauxite ores (in rotary kilns) reduces transportation cost, therefore, long single story gable roofed building hold the ore before processing. Rod or ball mills crush and screen bauxite ore (containing aluminum oxide) to the required consistency. Digestion takes place in the autoclave building. The autoclave building is an irregularly shaped stepped structure with full length ventilators in the uppermost section. Rarely, lattice framework surrounds open air digestors (tall cylindrical tanks collocated with flash cooling tanks). Here the slurry (a mixture of ore and caustic soda) reacts with superheated pressurized steam (170°C at 100 psi in the autoclave) and the ore dissolves. The caustic soda (sodium hydroxide) and the alumina (hydrated aluminum oxide) react forming a solution of sodium aluminate (sodium aluminum silicate) and insoluble impurities (silica, titanium and iron ores).

Figure 3.2: Alumina Industry Flowchart

Figure 3.3: Processes at Alumina Plant

Filtration occurs in the filter building, usually situated next to the autoclave or precipitation building. It is a long rectangular sawtoothed roof structure with many ventilators. Settling and washing tanks and filters remove the waste material (red mud) from the slurry. Thickening removes excess water before filtration of the wastes from the mixture. Thickeners are numerous low cylindrical tanks with agitators located between the autoclave and filter buildings. First filter tanks separate most of the red mud from the sodium aluminate. Next, passage through a series of wash tanks (using water) removes any remaining aluminate from the mix. Pumps transfer the waste material to the disposal area (red mud lake). The green liquor (overflow from the tanks) is a mixture of water and sodium aluminate. Filter presses (located in the filter building) remove impurities from the green liquor (using large cloth filters). Heat exchangers cool the green liquor before transfer to the precipitation building.

Precipitation produces aluminum hydrate from the green liquor. The precipitation tanks are tall conical bottom silo-like structures arranged (more than 100 tanks) in rows and columns. Each tank is 7 meters (24 feet) in diameter and up to 30 meters (100 feet) tall. The structure covering the tanks has numerous vents on the gable roof tops (frequently largest structure at the plant). The sodium aluminate decomposes into sodium hydroxide and aluminum hydroxide as cooling progresses. The cooling liquid in the tanks precipitates aluminum hydrate

Figure 3.4: Alumina Reactions

crystals that settle out of solution. Hydrate aluminum crystals (from storage silos at the end of the precipitator building) seed the solution, aiding in the rapid formation of additional crystals.

Hydroxide thickeners separate the alumina crystals. The hydroxide thickeners are tall cylindrical tanks with dome roofs. Multiple effect evaporators recycle the remaining liquid (caustic soda) back to a 50% caustic soda solution. Caustic soda storage tanks retain the caustic soda until use at the autoclave section. The precipitation period is 36 to 48 hours.

Gas fired rotary kilns heat the resulting crystals to 1100° C (2012° F) in the calcination process. Rotary kilns are long parallel tubes with buildings at both ends. The typical rotary kiln is 3 meters (10 feet) in diameter and 75 meters (250 feet) long. The building nearest the precipitation building houses the furnaces and has numerous stacks, vents, and dust control equipment. The building on the opposite end will have a light appearance due to settling alumina dust. The heat drives off water, leaving pure alumina (aluminum oxide). The alumina can be stored in silos before transport or processing at the aluminum plant.

The Lime Soda Sinter (also known as the Combination process) process is an addition to the Bayer Alumina process. This process treats low grade aluminum

Figure 3.5: Storage at Alumina Processing Plant

ores containing high percentages of silica. The process reclaims alumina (combined with silica during digestion). Instead of discarding the red mud, calcining (in rotary kilns) with limestone and soda ash produces additional sodium aluminate. Crushing and leaching allows recycling the material back through the digesters. The process produces brown mud waste instead of red mud waste.

Aluminum Metal

Aluminum reduction is by the electrolysis of alumina in a solution of molten cryolite (sodium aluminum fluoride, a snowy white mineral). The two main reduction methods are the Hall-Heroult and the Soderberg processes. The Hall-Heroult process uses a pre-baked carbon anode and the Soderberg process uses a continuous anode. The process used only affects the configuration of the electrode plant associated with the aluminum plant. Some modern innovations in aluminum production include a Hoopes cell process producing a very high purity aluminum metal, a low temperature method utilizing chlorine in a sealed reduction cell, and a thermal reduction method producing a low quality aluminum metal product.

Main components of an aluminum plant are the potrooms (long parallel buildings), cryolite and alumina storage, rectifier and casting buildings, carbon electrode plant, and the fluorine recovery unit. Raw materials include alumina,

Figure 3.6: Aluminum Processing Plant

Figure 3.7: Aluminum Product Flow

cryolite, carbon (to replace electrodes), and electricity. Tall cylindrical silos store both the alumina and the cryolite. The alumina silo is the larger of the two. One silo of each type serves two potlines. Often conveyors connect the silos across the top of the potroom.

Electrolysis is the reduction process for aluminum production. Large rectangular pots (with carbon linings as electrodes) accomplish the reduction. The potrooms house one or two long lines of electrolytic cells (potlines). The potroom is a gable roof structure with monitors. A plant usually has a series of potrooms to house all the potlines. Each potroom (which may be in excess of 300 meters long) houses several hundred cells. Each cell produces around 400 kilograms (900 pounds) of aluminum in a 24 hour period.

Rectifiers, located at the end of the potroom, convert alternating current to direct current. The rectifier building can be a long low flat roofed building (with or without ventilators) across the end of the potrooms. The rectifiers and transformers may be situated along the side of the building rather than within a structure. Most plants have a substation between the rectifier building and the power transmission lines.

Carbon electrodes, lowered into the cell, provide a path for the direct current flow. This heats the cryolite in the cell. Hoppers, situated directly over the cell, dump alumina once the cryolite melts. The mixture forms a crust that must be broken to allow total melting of the alumina. The alumina and cryolite mixture melts at 960°C (1760°F) and produces molten aluminum, fluorine, and oxygen.

Processing of the collected gases recovers fluorine. The recovered fluorine produces additional cryolite after recycling. The fluorine recovery building is a small compact building, located at the end of the potroom (or between potrooms), with waste gas stacks.

Figure 3.8: Aluminum Reactions

Figure 3.9: Aluminum Industry Flow Chart

Collection plates remove the molten aluminum from the melt. Crucibles transfer the aluminum to the casting building for production of foundry ingots, or, after treatment in holding furnaces, cast into ingots. The casting house is a long ventilated gable or flat roofed structure. If the casting house is a separate structure from the potrooms, a conveyor system will link the two structures. The holding furnaces, within the casting building, heat the aluminum (pure aluminum melts at 658° C), allowing dross (waste floating to the top) removal. Any alloying material

(copper, magnesium, manganese, zinc, silicon, or nickel) is added at this time. Small stacks indicate the presence of holding furnaces. The ingots are in pig, billet, or slab form. Normally, the plant uses open storage for ingots awaiting shipment. Some aluminum plants have aluminum rolling mills collocated with the complex. The rolling mill complexes are very long buildings with ventilated gable roofs.

The Hall-Heroult anode is a solid anode suspended in the electrolytic solution. The Soderberg anode is a carbon paste (coke, tar, and pitch) filled container immersed in the bath. The paste melts into the solution,

Figure 3.10: Aluminum Metal Production

Figure 3.11: Aluminum Reduction Plant

acting as an anode for electrolysis. The electrolytic process produces .45 kilogram (1 pound) of aluminum from (2 pounds) of alumina. During this process, oxygen, liberated from the alumina, consumes .35 kilogram (.75 pound) of carbon from the electrode. Processing requires continual replacement of the carbon. Petroleum coke or anthracite coal provides a carbon source for electrode production. The carbon electrode plant producing the electrodes is a long dark toned structure with numerous ventilators. The carbon electrode plant (Hall-Heroult) configuration is several parallel buildings with a building at each end. The carbon paste plant is one building with either a waste gas stack or ventilation system. Additional equipment at the paste plant includes tanks, silos, conveyors, and a rotary kiln. This equipment can be housed within the one building (or not).

Figure 3.12: Reduction Pot Types

Copper

Copper is one of the most important nonferrous metals. The pure metal, alloying, and industrial chemical industries use large amounts of copper. Copper's electrical properties (thermal and electrical conductivity) make it invaluable in electrical industries. The processing for native copper (naturally in metal

form) involves crushing, washing, and smelting (resulting in the end product of cast ingots). The smelting (with coke) of oxide and carbonate ores yields blister copper. The processing sequence for sulfide ores first involves smelting the ore, forming sulfide matte. Converting the matte (with lime and air) yields blister copper. Electrolytic refining of blister copper yields pure copper. Slimes (the by-product of the electrolytic anodes) yield accessory gold and silver metals after additional processing.

Usually the copper mine, ore concentration plant, and the copper smelter are collocated. Local economics determine the location of the copper refinery. Copper plants are leaching type or smelting type (seven different types of smelter furnaces). Leaching is a hydrometallurgical process (using liquid solvents) and smelting is a pyrometallurgical process (using fire). Identification features of the copper plant include close association to the mine (usually a large open pit), tall stack emitting dense white smoke, slag piles, and either a waste pond or a sulfuric acid plant. Additional features include roasting and smelting buildings, casting building, a substation, and the electrolytic refinery (with tankhouses).

Figure 3.13: Copper Ore Concentration

Figure 3.14: Copper Plant Components

**BLANK
PAGE**

Figure 3.15: Copper Processing Flow Chart

359

Figure 3.16: Copper Production Flow

Processing

The first step in copper ore processing is the removal of gangue at the ore concentration plant. Roasting removes sulfur dioxide ("SO₂") from the ore. Most roasters (roaster buildings) are the multiple hearth type, but newer plants use the fluid bed roaster. Removal of the sulfur dioxide reduces air pollution and provides a source for the production of sulfuric acid (acid plant is a criss-cross of piping, absorbers, converters, and tankage). Sulfuric acid is a leaching agent for copper ore processing and resale of the acid also defrays the cost of ore processing.

Roasting

The roaster building is a tall, rectangular, gable roofed, monitored structure with conveyors leading from the ore storage area. An extensive large flue system leads from the roaster building to the waste gas stack. One or two 90-180 meters (300-600 feet) tall waste gas stacks disperse gases and smoke at the plant. The flue system consists of cylindrical or rectangular ductwork connecting the buildings to the stack. Either a baghouse or a Cottrell precipitator (small building situated along the flue system) recovers copper dust from the waste gases.

The multiple hearth furnace is a tall cylindrical structure composed of several horizontal brick-lined hearths arranged vertically. Ore enters from the top, and heats, releasing sulfur fumes. Rabble arms push the ore to the outside of the hearth. Here, the ore falls down to the next level. Rabble arms push the ore to the center, where it falls down another level, and so forth. Air, blown counter to the feed, mixes with the sulfur, forming sulfur dioxide. The product of the roaster, calcine, proceeds onward to the smelter for additional processing. The waste gases pass through waste heat boilers for heat recovery. The sulfuric acid plant recovers the sulfur dioxide to produce sulfuric acid. The tall waste gas stack disposes of the rest of the gaseous material.

In the fluid bed roaster, air, blown from the bottom of the roaster (through tuyeres) suspends the ore feed (dropped through the top of the roaster). The suspended ore heats and reacts, liberating the sulfur from the ore. The greatest advantage for the fluid bed roaster is the minimal number of moving parts in the system. The greatest disadvantage is the retooling cost for older plants. The treatment for the calcine and the sulfur dioxide output from the fluid bed roaster is the same as the multiple hearth roaster.

Smelting

The next step in copper ore processing is the smelting of the calcine. Two smelter categories encompass seven types of furnaces. The first smelter category uses one of four standard furnaces (electric furnace, Momoda blast furnace, flash furnace, or reverberatory furnace) producing a copper matte. The copper matte produced from these smelters requires additional purification in converters. The second category uses a continuous furnace (Noranda, WORCRA, or Mitsubishi furnace) to produce a very high grade copper matte. This high grade matte doesn't require additional converter processing.

The smelter is the largest structure at the copper plant. The building is a long tall gable roofed structure. The smelter has the roaster building at one end and a converter and waste heat section at the other. Additionally, rail tracks lead from the smelter to the slag piles, another set of tracks provides furnace charges, and a flue system links the smelter to the waste gas stack.

Sintering fuses fine-grained ore concentrates before smelting. A mixture of fine coal or coke and the ore passes over a gas flame carried on an endless grate. Some sintering machines perform a dual function of roaster and sinterer.

The two most common smelters use the reverberatory furnace and the flash furnace. In the oil or gas fired reverberatory furnace, the calcine, mixed with silica flux, heats to 1100° C (2012° F). The ore melts, forming copper matte (copper with impurities), slag, and sulfur dioxide gas. The slag (composed of silica, iron oxide, and alumina) floats to the top. The tapped slag is disposed of on the slag pile. Sulfur dioxide gas, separated from the gaseous waste, forms sulfuric acid at the acid plant. The remaining gases vent to the atmosphere through the stack. The tapped copper matte goes to the converter for further purification (forming blister copper). Or, casting at the casting building produces low grade metal.

Figure 3.17: Copper Smelter

Photo Interpretation Training Course

The flash furnace smelter combines roasting and smelting in one operation. Additionally, the furnace produces a high sulfur dioxide (6-10%) content, perfect as primary acid plant feed. Fluxed ore concentrates, fuel, and oxygen or pre-heated air injected into the reaction chamber creates an exothermic oxidation reaction. The settler of the furnace collects the particulate material from the reaction. In the settler, the matte and slag separate.

The blast furnace is another method of copper smelting. The furnace charge consists of ore concentrates, coke, converter slag, and briquetted recovered dust. The ignited fuel heats and melts the charge. Air (not pre-heated) injected into the furnace both supports combustion and oxidizes iron and sulfur. Converter slag, acting as a flux, combines with impurities, forming slag, which rises to the top of the charge. The heavier matte sinks to the bottom of the furnace.

Converter

All the standard furnaces require a converter in the next stage of copper ore purification. Location of the converter building (a long rectangular gable roofed structure) is between the smelter and the electrolytic refinery. The casting building is a small building next to the converter building.

A silica flux and the ladle collected matte (at 1100° C) charge the converter. Air, blown into the matte, oxidizes the impurities (mostly iron oxides and sulfur). Tapping of the molten copper occurs when the converter is half full. This molten copper (blister copper) is of 98.5% purity. Additional refining produces copper of higher purity.

Refining

Refining the blister copper from the smelter by fire refining yields 99.5% pure copper. Electrolytic refining yields copper of 99.9% purity.

Fire refining (anode and fire refining furnaces) eliminates oxygen and sulfur impurities from the copper. An anode furnace accepts the still molten blister copper. First injected air drives off the remaining sulfur. Then a mixture of coke and either green logs (green timber) or hydrocarbon gas added to the copper removes oxygen from the copper. Blister copper, mixed with soda ash, melts in the reverberatory furnace in fire refining. The soda ash removes arsenic and antimony impurities. The refined copper is cast into ingots and shipped or cast into anodes for electrorefining. Fire refined copper is not suitable for electrical use but is suitable for structural use.

Electrolytic refining yields the highest purity copper metal. Electrolytic refining takes place in the tankhouse. This is a single story, multiple-bay structure with numerous roof vents and possibly a rectifier or substation section. Additional associations include a rail-served storage yard and the casting building.

Figure 3.18: Electrolytic Refinery

Direct current flow acts on the cast anodes and thin copper sheet cathodes, placed in a sulfuric acid and copper sulfate bath (tank). The copper from the anode dissolves and re-deposits on the cathode sheet. Impurities remain in solution or drop to the bottom of the tank as slime (mud). Gold, silver, and platinum recovery plants remove accessory metals from the slimes. A reverberatory furnace melts the cathodes (poled with green logs) for casting and shipment.

Leaching

There are four leaching processes that differ only in the location of the ores (that are being leached). The chemical used is usually sulfuric acid. Dump leaching is leaching of the waste ores from a mine (acid poured on the mound of ore). Heap leaching is leaching of oxide ores on a prepared surface (so acid doesn't leak into the ground). Flotation cannot separate oxide ores of copper. In place (in situ) leaching is leaching of the ores while still in the ground, usually on very porous ores with an impervious rock layer beneath. The fourth method is vat-leaching. Agitator equipped tanks of sulfuric acid (and ferric sulfate in some cases) leach the ores.

Figure 3.19: Copper Refinery

Figure 3.20: Copper Leaching Flow

Vat leaching consists of a series of large rectangular or cylindrical tanks covering a large area. Identification of dump, heap, and in-situ leaching is difficult. The only indication is a pipeline carrying sulfuric acid to the waste ore piles. Additional components include a sulfuric acid plant, substation, and tankhouses.

Two methods separate the copper from the acid solution for production of the copper metal. The first is precipitation (or cementation) of the copper from solution followed by smelting. The second is the electrowon process (recovery of metals by electrolysis). Solvents extract the copper from the leachate (identified by a series of 10-20 low rectangular buildings) and electrowinning removes the copper from the solvent-based solution. Or, electrowinning produces copper directly from the leaching solution.

Precipitation separates copper from the copper and acid solution for dump, heap, and in-situ leaching. The solution, forced upwards through scrap iron in a cone precipitator or launder, precipitates the copper (iron replaces the copper in the solution, leaving the copper free to fall out of solution). Standard smelting and refining produce copper metals from the resulting cement copper.

The product from vat-leaching goes directly to the tankhouse for electrowinning (because the solution has a very high copper concentration). The electrolytic refining process is slightly different. The anode is lead rather than copper, but the cathode is still a copper sheet. The solution provides the copper metal for the process rather than the anode. The product of this process is suitable for structural, sheeting, and alloy production (but not electrical uses). The solvent extraction process produces electrical quality copper.

By-Products Recovery

Roaster dust and gases yield arsenic and sulfuric acid after recovery operations. The sulfur dioxide gases yield sulfuric acid at the sulfuric acid plant.

Electrolytic solutions and slimes yield addition elements. Sulfuric acid leaches the dried slimes. The leached slimes, soda ash, and sodium bisulfate charge a smelter. The resulting slag carries selenium and tellurium. The remaining metal in the smelter furnace is high in silver, gold, platinum, and palladium. Electrolysis uses anodes, cast from the metal, in recovering these elements.

Electrolytic cells, equipped with insoluble anodes and copper cathodes, recover any remaining copper from the contaminated electrolytic solutions. Purification tanks (using reagents, controlled temperature, and controlled acidity) precipitate various impurities. Filtering, drying, and refining produces (from the precipitates) arsenic, antimony, bismuth, cobalt, and nickel.

Gold

Uses of gold include jewelry (75%), medium of exchange, medicine (7%—chiefly dentistry), industry (electrical conductors and electronic components such as integrated circuits and contacts), and a minor use in glass production of high grade optical components (such as IR sensitive mirrors for optical systems).

Gold occurs as native metal (free metal) in placer (gravel) or vein (as inclusions in quartz) deposits. Gold also occurs as the telluride ore sylvanite (Ag_3AuTe_2).

Gold occurs as an accessory (minor constituent) mineral in lead and copper sulfide ores. The gold ores contain little gold (in the range of 15 grams per metric ton).

Refer to the sections on copper and lead processing for a discussion of secondary metal recovery of gold from sulfide ores. The processing of gold ores involves normal ore concentration methods (refer to the section on mining), producing an impure gold metal containing copper, silver, and several other base metals.

Purification of the gold includes melting and oxidizing, removing the base metals and the silver. The Miller process purifies gold through melting and chlorination, which also removes the base metals and silver. Treatment of silver containing gold metal is through the Wohlwill process. The Wohlwill process purifies the gold by electrolysis of the gold chloride in a HCl solution (hydrochloric acid). The alloy (gold and silver cast material) forms the anode and pure gold forms the cathode. Electric current deposits the gold onto the cathode. The silver forms a silver chloride and remains as the anode.

Most gold processing plants are located near the mine. They look like a small compact ore concentration plant with additional buildings containing the casting houses, electrolytic cells, and chlorinating sections.

Lead

Lead metal usage is in the top four of all metals. Because lead is a health hazard and is very toxic, processing requires careful consideration. Uses for lead include alloying, solder, paints and coatings, and the production of printing type, batteries, and shot for ammunition.

Figure 3.21: Lead Ore Concentration

Lead ore concentration includes crushing, grinding, classification, and flotation. The concentrated lead ore contains 45% to 60% lead, 0% to 15% zinc, 0% to 3% copper, and 0% to 2% antimony. The ore also contains sufficient traces of gold and silver metals to warrant recovery. A zinc plant may be collocated to the lead plant since lead and zinc ores are often found intermixed.

Roasting

The lead ore contains 10% to 30% sulfur that must be burned off before smelting. Removal of the sulfur compounds is by roasting and/or sintering depending on the concentration of the ore. High concentration lead ores require a roasting operation to remove sulfur. The roaster building is a long slender gable (or sloping) roofed structure with a continuous monitor. A conveyor transfers ore from the ore storage area and another conveyor transfers roasted ore to the sintering facility. A pipeline connects the roaster building to the sulfuric acid recovery plant (if one is present). The roaster can remove only part of the sulfur when handling highly concentrated lead ores. To prevent the concentrated lead ore from melting and clogging the roaster, the operational temperature of the roaster is maintained below 750° C (1382° F). The lowered temperature doesn't remove all the sulfur.

Figure 3.22: Lead Processing Flow

Figure 3.23: Lead Smelter and Pyrometallurgical Refining

Figure 3.24: Lead Processes

Sintering

The sintering facility removes the remaining sulfur from the lead ore concentrates (now in the form of lead sulfates). The sintering building has a similar appearance as the roaster building with the addition of several short stacks and monitors. A flue connects the large baghouse to the sintering building. The flue system consists of long cylindrical or rectangular pipes. The baghouse is a large flat roofed building. Another flue connects the sintering building to the extremely tall waste gas stack. The sintering building is normally situated next to the blast furnace. The sintering process involves placing the concentrates, mixed with fine coal or coke, on a moving grate. A gas flame ignites the mixture and drawn air oxidizes and sinters the mixture forming lead oxide. The sulfur dioxide and dust from the burning charge pass through flues to the baghouse. The baghouse recovers lead dust for return to the sinterer. The acid plant recovers the sulfur dioxide gas (or waste gas stacks vent the gas to the atmosphere).

Then the blast furnace smelts the lead oxide, freeing the lead metal and gathering the impurities in a slag. The blast furnace is the tallest structure at the lead plant. The structure is a gable or flat roof building with either 4 to 7 short waste gas stacks or a continuous monitor. Flues connect the blast furnace to the baghouse. A conveyor carries roasted and sintered ore from the roasting or the

Figure 3.25: Flue System at Lead Plant

Figure 3.26: Slag Pile at Lead Plant

sintering building. The blast furnace usually has a shed extension. A compressed gas pipeline supplies air for the furnace operation (from the compressor building). The sintered ore, mixed with coke and a lime silica flux provides the charge for the blast furnace. The ignited ore, supported by a compressed air flow, burns, forming carbon monoxide. The carbon monoxide reduces the lead ore to a molten lead bullion. The molten lead settles to the bottom of the furnace and the slag rises to the surface. The slag fuming plant recovers the zinc oxide content from the slag and the remaining slag is sent to the slag pile for disposal. Railroad tracks carry the slag from the blast furnace to the slag dump (dark, toned pile).

A drossing kettle reduces impurities in the lead bullion (primarily in the form of copper) by controlled cooling to 327° C (621° F). The impurities oxidize during the cooling and rise to the surface of the lead. A perforated disc skims the impurities from which copper and other by-products are recovered.

Refining

Pyrometallurgical (fire refining) and electrolytic (Betts process) are the two methods used for refining the lead bullion after drossing. Pyrometallurgical refining involves heating the copper free lead. Zinc dust, added to the melt, causes arsenic and antimony impurities to form a dross (and softening the lead). Additional smelting produces antimonial lead (hard lead) from this dross. Furnaces heat the remaining softened lead until it reaches a molten state. Added zinc to this melt causes gold and silver impurities to separate forming a dross for removal. The drossing and refining building is a low irregular gabled roof structure of low to moderate height. The building has either continuous monitors or numerous short stacks. The structure is near (or attached to) the blast furnace

or casting building. Flues connect this building to the baghouse. The dressing and refining building contains the dressing and by-products kettles and sometime a casting wheel.

Canada and Peru are the primary users of the electrolytic process of refining. A solution of fluosilic acid and lead fluosilicate electrolyze lead bullion anodes. Direct current, passing through the solution, causes the deposition of pure lead on the cathodes. Some impurities remain on the anode and the rest enter the electrolytic solution. Reagent[®], controlling the temperature and acidity, purify the electrolytic solution. The separation of the impurities from the solution allows the production of a 99.85% purity lead product. The electrolytic refining building is a large (almost square) structure with nearby substation, rectifier buildings, and electrolytic tanks.

Casting

Casting forms lead pigs from the refined lead bullion. The casting building is a low to moderate height rectangular gable (or flat) roofed structure. The casting shed has either a continuous monitor or numerous ventilators. The casting shed is situated adjacent to the dressing and refining sections. Railroad tracks lead to the casting and storage section.

Figure 3.27: Lead Refining, Electrolytic Method

Magnesium

Magnesium and its alloys are extremely strong materials able to withstand high temperatures. The aerospace and vehicle production industries use most of the magnesium production in construction of structural members, engines, and sheets. Explosive, nuclear, and incendiary industries also use magnesium metal. The organic and in-organic chemical industries make use of magnesium in chemical processes.

Magnesium metals have a high affinity with oxygen. The ores of this metal require reducing (of their chlorides) at high temperature in a vacuum (or an inert atmosphere).

Dolomite, magnesite, and carnallite ores contain magnesium. Seawater, natural brines, and salt deposits also contain magnesium. Sea water extraction is the source for half of metallic magnesium, dolomite is the source for almost all the rest.

The two main processing methods are electrolytic (chemical processing) and electrothermic (mechanical processing) processing. Electrolytic processing accounts for 80% of magnesium production. The Dow and the Farben electrolytic processes differ only in the electrolytic cell configuration. The Dow and Farben electrolytic processes produce magnesium from magnesium chloride. Sea water and lime (oyster shells if available) mixed in large settling tanks precipitate insoluble magnesium hydroxide. The filtered hydroxide treated with hydrochloric acid forms magnesium chloride. Electrolysis converts the fused material into chlorine gas and molten magnesium. Scrubbing towers recover the gas and the magnesium is cast into ingots.

Figure 3.28: Magnesia Flow Chart

The carbothermic and ferrosilicon processes are electrothermic processes. Magnesium oxide and carbon reduce to carbon monoxide and magnesium vapor in the carbothermic process. The vapor condenses to an impure magnesium dust. The reheated briquetted magnesium dust vaporizes and condensers produce pure magnesium metal. In another process, the ferrosilicon process, the magnesium oxide (dolomite), mixed with ferrosilicon, heats in a vacuum. The condensed magnesium gas yields metallic magnesium ready for casting.

Magnesia Production

Magnesium oxide (magnesia) for magnesium metal production comes from magnesia plants. The location of the magnesia (from brine) plant is usually along the coastline. Well brine and salt deposits (bitterns) also provide a magnesium source. A refractory brick plant, using magnesia, may be located near the magnesia plant. Processing 712,000 liters (188,000 gallons) of seawater yields 900 kilograms (1 ton) of magnesia.

Slaked lime (calcium hydroxide) is the reagent used in extracting magnesia from brines. Mixing crushed calcined (roasted) seashells (light-toned stockpile),

Figure 3.29: Magnesia From Brine Plant

Figure 3.30: Magnesia From Brine Plant Components

limestone, or dolomite and water produce the slaked lime. If dolomite supplies the slaked lime, 356,000 liters (94,000 gallons) of seawater yields 900 kilograms (1 ton) of magnesia, because the dolomite supplies both calcium hydroxide and magnesium hydroxide. Most plants have a separate rotary kiln for roasting the lime. The kiln is a set of long parallel tubes with hoppers at one end and a filter building on the other. Storage of the slaked lime is in a small tank (slaker) located near the raw material storage silos or bins (i.e., raw material storage for slaked lime production).

Large tanks (hydro treaters) hold the brine, pumped from their source (seawater). When the slaked lime and the brine mix, the soluble bicarbonates and impurities precipitate. Rakes and pumps remove the by-products from the center of the tank. The clarified brines, containing magnesium hydroxide, flow over the edge of the tank and on to the flocculator tank.

The addition of calcium hydroxide causes the settlement of the magnesium hydroxide in the flocculator tank. The flocculator is a small cylindrical or rectangular tank. Pumps send the settled magnesium hydroxide to the thickening tanks and the remaining brines to the waste pond (for disposal). The waste pond is a large, light-toned area.

Fresh water washes the magnesium hydroxide in the thickening tanks. The large thickening tanks are typically in groups of four. Each tank has an arm (or rack) extending to the center (central discharge point). The treatment of the fresh water (before use in the thickening tanks) removes bicarbonates by the applica-

tion of slaked lime. A single fresh water hydro treater tank performs the treatment and a single fresh water storage tank stores the treated water. The fresh water hydro treater is a small dark-toned tank. A counterwashing system separates the magnesium hydroxide from the impurities. The fresh water moves in a direction of flow opposite to the flow of the magnesium hydroxide. At the end of the treatment process pumps send the wash water to the waste pond for disposal. The dewatering tank (or alternatively the filtering section of the rotary kiln) removes the excess water from the magnesium hydroxide slurry (from the last tank in the series).

Calcining of the magnesium hydroxide is the last stage in the magnesia process. Rotary kilns dry the magnesium hydroxide (water escapes as steam). Large bins or silos store the finished magnesium oxide (magnesia) prior to shipment or further processing at the magnesium plant.

Magnesia obtained by calcining magnesite (magnesium carbonate) yields a material suitable for refractory and insulating materials (without additional purification or processing).

Magnesium

Magnesium chemical processing (electrolytic) produces most magnesium metal. Magnesia, carbon, and chlorine produce magnesium metal in the Farben electrolytic process. Magnesia combined with peat moss and carbon (in the form of petroleum coke or anthracite coal) produces a porous pellet. The pellets, mixed with magnesium chloride, forms a paste. Tunnel kilns (rotary kilns) dry the pelletized paste.

Figure 3.31: Electrolytic Process Flow

Figure 3.32: Pellet Preparation Area

Figure 3.33: Farben Electrolytic Cell Magnesium Plant

Figure 3.34: Electrolytic Cell For Magnesium Metal Production

Chlorinators (tall, cylindrical, electrically heated furnaces) heat the pellets and a chlorine atmosphere to 900°C (1652°F). An associated chlorine and caustic soda plant supply the chlorine gas. The magnesium reacts with the chlorine, forming molten anhydrous magnesium chloride. Once an hour the tapped magnesium chloride charges the electrolytic cells. Scrubbing towers, clarification tanks, and coolers recover hydrochloric acid and anhydrous magnesium chloride from the exhaust gases (consisting of hydrochloric acid, anhydrous magnesium chloride, carbon monoxide, and carbon dioxide) of the chlorinator. The acid neutralization plant produces magnesium chloride from the recovered materials.

Gas-fired furnaces heat the mixture and the cells operate at 670°C to 730°C (1238°F to 1350°F). Direct current flow in the electrolytic cell produces molten magnesium and chlorine gas from the anhydrous magnesium chloride electrolyte (added sodium chloride increases conductivity and lowers the melting point of the solution). The scrubber recycles the released chlorine gas from the cell.

Modern plants produce 99% pure magnesium, suitable for immediate casting. Older plants produce 85% pure magnesium and additional refining in crucible furnaces produces higher purity magnesium metal. The crucible furnace heats the magnesium and flux charge to 1100°C (2012°F), the impurities sink and the pure magnesium rises to the top of the melt. The pure metal is then ready for casting into billets, slabs, or ingots.

Chlorinating magnesium hydroxide with hydrochloric acid produces the magnesium chloride used in Dow electrolytic cells. Magnesium hydroxide slurry and a dilute hydrochloric acid react, forming magnesium chloride. Submerged-burner evaporators remove excess water from this mixture, increasing the magnesium chloride concentration. Shelf dryers crystallize (with hot air) the concentrated

Figure 3.35: Dow Electrolytic Cell Magnesium Production

Figure 3.36: Electrothermic Process Flow

417

Figure 3.37: Carbothermic Magnesium Plant

magnesium chloride before charging into the Dow electrolytic cells. Associated hydrochloric acid and chlorine and caustic soda plants recover the by-products and produce the raw material necessary for this process.

Briquetted magnesium oxide, mixed with carbon and pitch, produce magnesium metal in the carbothermic (electrothermic) process. Electric arc furnaces reduce the briquettes to metallic magnesium vapor and carbon monoxide. Hydrogen or natural gas rapidly chills the evacuated gases (from the arc furnace). The chilling reduces the amount of magnesium oxide produced in the process by dropping the gases below the critical reaction temperature. Electrostatic precipitators collect the magnesium dust, magnesium oxide, and carbon particles from the condenser. Briquettes (60% to 65% pure magnesium), made from the collected dust, charge a cylindrical retort (equipped with a water-cooled condenser). An electric resistance furnace heats the retort to 750° C (1380° F) under a constant vacuum. The magnesium

Figure 3.38: Ferrosilicon Magnesium Plant

sublimes and condenses in the top of the retort. After 72 hours the retort is cooled and the magnesium is recovered. Crucibles re-melt the magnesium for casting.

Another electrothermic process, the ferrosilicon process (virtually obsolete) uses calcined crushed dolomite (calcium magnesium carbonate) mixed with ferrosilicon to produce magnesium metal. Electric resistance furnaces (or gas-heated furnaces) heat the dolomite and ferrosilicon mixture (in a retort) to 1150° C (2100° F) under a vacuum. The calcium magnesium oxide combines with the ferrosilicon, forming waste calcium iron silicate and magnesium metal vapor. A condenser at the end of the retort cools the vapor and differential contraction separates the metal from the waste.

Electric arc furnaces at ferrosilicon plants supply the ferrosilicon. A mixture of carbon and siliceous iron ore or scrap iron and silica sand charge the furnace. The furnace reduces the mixture to metallic silicon and iron, which combine to form ferrosilicon. Similar plants using electric arc furnaces produce ferrochrome, ferromanganese, ferrovanadium, and ferromolybdenum.

There are few magnesium plants in the world. Most use the electrolytic process and are difficult to identify. Identifiable components are the chlorinating section, the rectifier annex, and the electrolytic cell building. The chlorinator section is a (40-50 feet) tall building housing the scrubbing towers and chlorinators. Unhoused chlorinator sections look like silos with pipes leading into the tops. The electrolytic cell section is a long narrow rectangular building with numerous roof vents. The rectifier section is a small flat roofed building with or without vents. Normally, a substation is nearby.

These components will be near to, or adjoined, each other. The typical arrangement is the electrolytic cell building in the center with the chlorinator section and the rectifier annex on opposing ends. A titanium plant may be collocated with the magnesium plant (magnesium used in titanium production).

Manganese

Manganese uses include alloying applications in non-ferrous metals such as copper and nickel, in the production of manganese alloy steel, and applications as a deoxidizing agent. Principle manganese ores are pyrolusite, braunite, hausmannite, and rhodochrosite.

Manganese processing methods include reduction or electrolysis of the oxide ore.

Reduction of the Oxide Ore

Ferromanganese (a mixture of 80% manganese and 20% iron) is the result of reduction of oxide ores. A blast furnace or electric arc furnace produces the reduced ore. The charge for the blast furnace includes manganese ore, carbon, and aluminum, magnesium, or sodium. The electric arc furnace charge is manganese ore, limestone, and coke. Both of these processes recover around 85% of the metal.

Electrolysis

Electrolysis yields high purity manganese metal. A roasted ore converts the manganese ore to its oxide (MnO). Leaching the MnO with sulfuric acid (H_2SO_4) yields a sulfate. Neutralization of the solution removes the iron and aluminum by precipitation. Electrolysis of the remaining sulfate solution yields 99.94% pure manganese metal.

Mercury

Mercury ranks in 10th in non-ferrous metal production. Uses for mercury include manufacture of electrical apparatus, use in mercury cells in the processing of chlorine and caustic soda, and paint manufacture. Additional uses are in pharmaceutical and agricultural chemical production.

The main mercury ore is cinnabar. Cinnabar contains 86.2% mercury. Flotation of the cinnabar ore raises the mercury concentration of the rock to 25-50%. Roasting the concentrate releases mercury in the form of gas. A distillation process recovers a condensate with a purity of 95% (for furnace plants) to 98% (for retort plants).

A refining process of distillation or filtering, oxidation, and acid leaching yields mercury of 99.9% purity. Triple distillation yields nearly pure metal for those applications with exacting purity requirements. Secondary recovery of mercury metals, mercury-bearing equipment, and amalgams yield around 20% of the domestic mercury production.

Nickel

Primary uses for nickel are in the production of stainless steel and high-nickel alloys (in the aerospace and steel industries). Additional uses are in nickel plating, castings, coinage, copper or brass product applications, chemical and petroleum industries. High grade nickel sulfide ores (especially pentlandite) are the major source of nickel. Low grade nickel ores occur in lateritic deposits. The nickel sulfide ores commonly occur with copper and iron ores.

Refining for nickel ores consist of pyrometallurgical or hydrometallurgical methods. A separate pyrometallurgical and hydrometallurgical method exist for each type (lateritic and sulfide deposits) of ore. The most common method of refining is the pyrometallurgical method, however, the most efficient method is hydrometallurgical refining. Products include nickel cathodes, pellets, powder, briquettes, ferronickel, nickel oxide, and nickel salts.

Nickel refining methods vary world-wide. In general the production flow for processing involves the following steps. Roasting partially removes sulfides from the ore. Smelting removes rock, leaving a copper-nickel-iron matte. The Bessemer converter removes the iron and sulfur. After magnetic separation and flotation, sintering the remaining nickel sulfide forms an oxide. The oxide is cast as anodes for electrolytic processing to form nearly pure nickel. Also the electrolytic process recovers accessory gold, silver, platinum, and several other metals.

Figure 3.39: Nickel Process Flow

Identification of the Nickel Refinery

Most nickel refineries consist of one or more tall waste gas stacks, an air separation plant, and electrolytic refining buildings. Both types of plants also have smelters and converter buildings. The lateritic ore nickel smelter has, in addition, one or more rotary kilns.

The rotary kilns used in lateritic ore smelting remove sulfur and oxidize the ore. The kilns consist of one or more long parallel tubes with buildings at either end. One building is the charge building, the other building houses the smelter and converter. The kilns slope gently downward in the direction of the process flow.

Roasting and sintering buildings smelt sulfide ores. The tall rectangular gable or flat roofed building has a conveyor leading from the ore storage area.

Smelting and converting buildings are used for all nickel ore processing. This is the tallest and largest building at the refinery. This is an irregularly shaped flat roofed structure with numerous vents or a continuous monitor. Railroad tracks lead from the building to the slag dump. Common smelter types for nickel ores are the electric furnace and the blast furnace. Rotary kilns lead to this building when processing lateritic ores.

Both the sulfide and lateritic ore processing plants use electrolytic refining. The electrolytic refining building is more common at sulfide ore plants. The long rectangular flat roofed building has numerous roof vents or monitors. A substation and rectifier building are located nearby.

An air separation plant is a common support facility. The plant produces nitrogen, oxygen, and argon from the atmosphere. The plant consists of a long rectangular flat roofed compressor building, a tall square (stepped appearance if collocated with the compressor building) cold box, and wet or dry gasometers for gas storage.

Pyrometallurgical Processing of Nickel Sulfide Ores

A multihearth furnace, fluid bed roaster, sintering machine, or rotary kiln partially roasts the sulfide concentrates. Roasting reduces the sulfur content by 50% and produces a mixture of copper-nickel-iron sulfides. Next, a reverberatory furnace, blast furnace, flash smelter, or electric furnace smelt the sulfide and flux mixture, forming an impure copper-nickel-iron matte.

In the converter, the matte and silica flux is blown with air, the silica flux removes most of the iron and some sulfur (as sulfur dioxide), yielding a sulfur deficient copper-nickel matte. After several days of controlled cooling, a grinding and flotation process separate the nickel sulfides from the copper sulfides (allowing separate processing of copper and nickel). Roasting the nickel sulfide yields a nickel oxide sinter for use in the steel industry. Or further reduction by an electrolytic (most common) or carbonyl method yields a purer product.

The electrolytic method involves immersing a crude metal (or nickel sulfides) anode and a thin starter sheet (of pure nickel metal) cathode in the electrolyte. Through electrolytic action the anode dissolves into the electrolyte solution. A purification train removes impurities after the solution are pumped from the cell. The re-introduced purified solution takes ten days to form 99.9% pure nickel metal on the cathode.

The carbonyl (Mond process) process refines the nickel by reacting the crude nickel and carbon monoxide at 100° C (212° F) forming nickel carbonyl. A decomposition tower heats the nickel carbonyl to 200°-300° C (392°-572° F). The decomposed nickel carbonyl deposits as 99.9% pure metal pellets on nickel shot.

Hydrometallurgical Processing of Nickel Sulfide Ores

An ammoniacal solution dissolves the nickel sulfide ores, forming nickel, copper, and cobalt amines. Heating the resulting solution precipitates the copper amines. Oxidation of the cobalt and nickel amines forms sulfates. The sulfate, combined with hydrogen, at high temperature and pressure forms 99% pure nickel metal powder.

Pyrometallurgical Processing of Nickel Laterites

The pyrometallurgical method of processing nickel laterites requires an enormous amount of fuel or electrical energy. Smelting the ore and flux (gypsum) produces an iron-nickel matte. Processing the iron-nickel matte is the same as for the nickel sulfide ores. The converter removes the iron impurities and electrolytic cells refine the nickel.

Figure 3.40: Pyrometallurgical Process Nickel Refinery

The production of nickel rondelles is by a roasting process. The roaster produces a nickel oxide from the iron-nickel matte. Grinding, compacting, and reducing (using charcoal in a muffle furnace) the nickel oxide yields 99% pure nickel rondelles. The muffle furnace typically is a long rectangular gable roofed structure with numerous short stacks. The rotary kilns lead into the side of the structure. The production of ferronickel involves smelting the nickel laterite without a flux and reducing the smelt with coke in electric furnaces. The resulting ferronickel has a 20%-50% purity.

Hydrometallurgical Processing of Nickel Laterites

Ammonia or sulfuric acid leaching is the process for hydrometallurgical refining of nickel laterites. The first step in the ammonia process is the reduction of the nickel oxide. Next, ammonia leaches the nickel and dissolves the nickel. Heating the solution precipitates nickel carbonate. Roasting converts the nickel carbonate into a nickel oxide product for use in the steel industry.

In the acid process sulfuric acid leaches the ore at high temperature and pressure. The temperature and pressure differential cause the nickel and sulfur to enter solution but prevents iron from entering the solution. Mixing with hydrogen sulfide precipitates nickel and cobalt sulfides from the purified solution. Refining the resultant nickel sulfide by a conversion process yields nickel sulfate. Reduction of the nickel sulfate with hydrogen produces a high purity nickel powder.

Platinum

Platinum occurs as native metal or more commonly as an accessory ore in nickel-copper sulfide ores. Uses for platinum include alloys for jewelry, scientific apparatus, and electrical contacts. A major use is as a catalyst in industrial applications.

Processing facilities for native metal deposits are basically an ore concentration plant. Refer to the sections on copper and nickel refining for a discussion of secondary metal recovery. The basic process involves smelting the copper-nickel ores, containing the secondary platinum metal. Anodes formed from the smelted material are electrically dissolved. Copper deposits on the cathode, nickel enters solution, and the platinum remains as a slime attached to the anode. Roasting the platinum slime removes the sulfides. Leaching removes any residual copper and nickel and the platinum precipitates from solution. Washing and drying the precipitate allows the material to be calcined to form nearly pure platinum metal.

Silver

Silver occurs as native metal, silver chloride ores, and simple or complex silver sulfide ores (as associated minerals with lead, copper, and zinc ores). Principle industrial uses for silver include photographic film, electrical contact, alloys, chemical, and battery manufacturing. Additionally silver finds uses in jewelry, sterling silver, mintage, and art.

Historically, silver processing included simple ore concentration of native metal, and amalgamation and cyanidation ore concentration and recovery. Modern silver processing is by secondary recovery from copper, zinc, and lead ores.

A typical process for silver recovery involves separating the copper, zinc, and lead ores. The silver ore is also separated if the silver grade is high enough. Otherwise, smelting of the lead and copper ores produces mattes, from which through electrolytic refining, the silver is recovered. When associated with copper and lead refining, look for an area containing electrolytic vats and refinery. This area may not be separate from the rest of the refinery but may be incorporated in the rest of the complex.

Leaching and electrolytic processes are used for the zinc ores. Processing of the residues of the electrolytic plant produces silver metal. When associated with zinc refining, look for a leaching area and an electrolytic vat building.

Refer to the sections on refining of copper, lead, and zinc for a more detailed explanation of these processes and components.

Tin

Tin ores occur as tin oxides and tin sulfides. The main uses for tin are in tin plating, alloys, solders, and chemical production.

Secondary tin recovery is much more extensive than the primary metal production. Tin recovery (from recycled materials) is through electrolytic or chemical methods.

Primary metal production of oxide ores is through ore concentration, roasting (forming oxides), and crude metal recovery from a blast furnace. Additional refining occurs in electrolytic furnaces.

Titanium and Associated Electrothermic Metals

Titanium, vanadium, zirconium, and their alloys are extremely strong materials able to withstand high temperatures. Steel production (ferroalloys) uses most of the titanium, vanadium, and zirconium production. The aerospace, military, chemical, and tool industries use these alloys in equipment production. The paint and pigment industries use titanium dioxide. The primary titanium ores are rutile and ilmenite. Almost all commercial deposits (at least at present) occur as rutile bearing sands. Dredges mine the sands; then gravity, magnetic, and electrostatic concentration methods yield a 95% purity titanium dioxide for additional processing.

Titanium, vanadium, zirconium, and magnesium collectively are referred to as electrothermic metals, due to the method used in processing the ores. Titanium, vanadium, and zirconium metals have a high affinity with oxygen. The ores of these metals require reducing (of their chlorides) at high temperature in a vacuum (or an inert atmosphere). The Kroll process produces titanium, vanadium, and zirconium. Titanium oxide, carbon, and chlorine react in a chlorinator, forming titanium tetrachloride in an exothermic reaction. Titanium tetrachloride and

Figure 3.41: Electrothermic Metal Production

Figure 3.42: Titanium Production

metallic sodium (or magnesium) reduce at 50°C (122° F), producing titanium metal sponge and sodium chloride (or magnesium chloride). When magnesium is used, the resulting magnesium chloride by-product is recycled through electrolysis for re-use in processing. A third method of titanium production is the direct electrolysis of titanium tetrachloride.

Zinc

Zinc metal is fourth in annual consumption and use. Major uses of zinc are in zinc metals and alloys, protective coatings, and chemical compounds. Zinc oxide uses include applications in chemical, rubber, and paint production. Zinc usually occurs in conjunction with lead ores as lead and zinc sulfides (sphalerite and galena). Secondary recoverable minerals to the lead-zinc ores include copper, silver, antimony, and bismuth. Zinc ore is separated from lead ore at the concentration plant located at the mine. The ores are finely ground and the ores separate by froth flotation. Whichever ore is not separated first is separated from the gangue by a second froth flotation pass. Two smelting methods of processing zinc are the oxide reduction and the combined lead-zinc processes.

Figure 3.43: Electrolytic Zinc Flow

The horizontal retort process is the oldest zinc smelting method, still accounting for 10% of world production. Small horizontal retorts roast the zinc ore. Coal is mixed with the concentrate and the mix is heated for 1-2 days. The zinc, in the form of vapor, is condensed and recovered. Several hundred retorts will be required in the process. A newer horizontal retort process uses fluid-bed roasters or sintering furnaces in place of the hundreds of smaller retorts. The vertical retort process is much less labor intensive than the horizontal retort method. In the vertical retort process, zinc sulfide ores mixed with coal are briquetted and charged into the vertical retort furnace. The continuous process is heated by gas,

driving off zinc vapors for condensation. A newer process uses an electric shaft furnace. Here, the roasted and sintered zinc ore is mixed with coke and fed to the furnace. The electric arcs melt the ore, freeing zinc vapor.

The two methods for simultaneously processing zinc and lead ores are the Imperial Smelting Process (ISP) and the Kivcet Process. The ISP uses a blast furnace to produce the zinc vapor and the lead is reduced at the same time. The Kivcet Process has finely ground lead, copper and zinc sulfides heated in a cyclone furnace by burning the ore with a stream of oxygen. The lead is reduced and collected. The zinc, mixed with slag, is reduced to zinc oxide vapor in an electric furnace. The oxide is reduced by carbon and the zinc vapor is condensed. The copper is recovered as a matte formed with the sulfur in the reactions, and is then reduced.

Plant Identification

Most zinc metal reduction occurs at an electrolytic plant. Key identifiers are the Cottrell precipitator building and stack, a stepped leaching and purification building, electrolyte tanks, and the electrolytic cell building with associated rectifiers and substations. The roaster building is a tall gable roofed structure with a continuous monitor. The roaster has conveyors leading from the ore storage and handling areas and flues leading to the sulfuric acid plant or waste gas stack. Often the plant is located on a hillside to take advantage of gravity during the production process. Associated with the plant may be a sulfuric acid production plant.

The leaching and purification section is a large stepped roof structure located below the roaster. The upper sections contain the leaching tanks and the lower sections contain the purification tanks. The upper section has numerous short stacks or vents. The structure also houses the thickeners and filters.

The electrolytic cell is a very large low building with vents or continuous monitors. Pipelines connect the leaching and purification building and the electrolytic cell building. Also present are substations, rectifier annexes, and electrolyte tanks (open or closed).

The casting building is a moderate sized gable or flat roofed structure with numerous vents or monitors. It is found adjacent to or near the electrolytic cell building. If the plant is on a hillside, the casting building will be the lowest structure. Storage and loading facilities are nearby.

Reduction can occur also at horizontal or vertical retort smelters. A pottery plant will be nearby for the horizontal retort smelter. Look for baghouses, waste gas stack with flue system, sulfuric acid plant, and slag piles. Zinc oxide may be produced by several processes. Look for buildings with rotary kilns, flue complexes, baghouses, and cooling columns. Zinc refining is accomplished using a reverberatory furnace (probably an additional building in the plant) or in distillation columns.

Figure 3.44: Electrolytic Zinc Plant

The Electrolytic Process of Zinc Production

Several processes can be used to convert the concentrated zinc ore into metallic zinc. Among the processes are electrolytic, horizontal retort, vertical retort, sterling, electrothermic, blast furnaces, and the American process. The most common process is electrolytic process which produces 75% of the world's zinc metal.

The first step is roasting, converting the zinc sulfide into zinc oxide, and ridding the ore of its sulfur content. The three roasting methods are the multiple hearth furnace, the fluid bed roaster, and the least common, the flash furnace. Refer to the section on copper roasting for a furnace operation description for the fluid bed and multiple hearth roaster. The flash roaster consists of two top hearths, two bottom hearths, and an open combustion chamber between the hearths. The concentrated ore passes through the feeder and dryer hearths to a ball mill where the ore is ground to a fine dust. The dust is returned to the combustion chamber, through burners situated below the drying hearths. The zinc ores burn to zinc oxide and waste sulfur dioxide gases. The zinc oxide exhausts through the bottom hearths. The sulfur dioxide can be wasted to the atmosphere or recovered at a sulfuric acid plant. Dust, associated with the waste gases, is high in cadmium (recovery at an associated processing section). Three methods can remove the cadmium dust from the gases. They are an electrostatic precipitator (Cottrell or other type), a bag house, or an expansion chamber built into the flue system. The most common and most efficient method is the precipitator.

Next the zinc oxide is mixed with 10%-25% sulfuric acid in leaching (and agitating) tanks. The piped slurry separates by gravity in thickening tanks. The solids are removed, filtered, dried, and sent to a lead smelter. The settled solids contain recoverable lead, gold, and silver. Purification tanks process the zinc sulfate solution. Added zinc dust and aluminum cause the precipitation of impurities such as cadmium, copper, cobalt, ammonia, and arsenic.

The refinery section consists of electrolytic cells. The cells use lead anodes and aluminum cathodes. Metallic zinc deposits on the cathodes as direct current passes through the zinc sulfate solution. The casting section of the plant strips the cathodes and casts the 99.9% pure zinc metal.

Zinc Smelting Processes

Several smelting processes also produce zinc metal from concentrated zinc ores. The three common zinc smelters are the horizontal retort, the vertical retort, and the electrothermic furnaces. The typical smelter uses roasters and sintering machines to prepare the ore for the smelter. The basic process for smelting is the same. The charge for the smelter, prepared in the charge mixing building, heats above 907° C (1665 F) in the smelter. Carbon from the coke in the charge burns, forming carbon monoxide. The carbon monoxide combines with the liberated oxygen from the zinc oxide, yielding carbon dioxide. The reduced metallic state zinc vaporizes and after cooling, forms molten zinc for casting or further refining.

Horizontal Retort Zinc Furnace

The horizontal furnace is a batch operation smelter. The retorts are cylindrical clay retorts which have open-ended conical clay condensers. A nearby pottery plant produces the retorts and condensers. The retorts, suspended in rows in gas-fired furnaces, heat for several hours. Blue dust (cadmium) collects in the condensers during the first few hours. The cadmium recovery section processes the recovered cadmium dust. As the zinc reduces, it vaporizes and passes into the condensers. The condensers collect the molten zinc. During the 24 hours required to fully process the charge, the molten zinc is typically collected 3 times. After processing the charge, the removed retorts yield slag for disposal or further processing.

Vertical Retort Zinc

The vertical retort furnace is a continuous operation. Baked briquettes composed of zinc, water, and a suitable binder form the charge for the gas-fired furnace. The reduced zinc collects in condensers and sumps as molten metal.

Electrothermic Furnace Zinc

The electrothermic furnace is also a continuous operation. A special sintering for the roasted ore concentrates provides an extremely pure charge for the furnace. The sintering involves drawing air down through the sinter cake mixture of ore and coke. The process frees any remaining sulfur. Lead and cadmium concentrate in the lower half of the sinter cake. Repeated sintering of the lower half yields pure zinc.

The sintered concentrates, silica flux, and coke form the charge for the continuous operation furnace. Electrical resistance heats the charge to the required temperature for reduction and vaporization. Cooled and condensed vapor yields the molten zinc metal for casting.

Zinc Refining

Electrothermic and electrolytic zinc do not require additional refining prior to use. The output from horizontal and vertical retort zinc requires refining prior to some uses.

Reverberatory Furnace

The reverberatory furnace maintains the temperature of the molten zinc above the melting point for one to three days. During this time zinc oxide and other impurities rise to the surface as dross for removal and recycling in the retort furnaces. Iron and lead impurities sink to the bottom for removal and recovery. Refined zinc is tapped and cast.

Distillation Columns

Distillation columns are sets of stills for refining the zinc. In the first column (kept above the boiling point of zinc) zinc oxide, iron, and lead remain in the liquid and solid phase. These impurities collect in the bottom of the column and are removed for recovery. The volatilized zinc passes into a second column

Figure 3.46: Horizontal Retort Zinc Plant

Figure 3.47: Vertical Retort Zinc Plant

maintained above the boiling point of cadmium. The cadmium passes into condensers for recovery. The zinc condenses in the column as molten zinc metal for removal and casting.

Zinc Oxide Production

Roasted and sintered zinc concentrates are the primary source of zinc oxide. Metallic zinc, lead smelter slag, and retort furnace slag also are a source for zinc oxide. Several methods produce zinc oxide but the basic process is the same.

Raw material, mixed with coke, charges the furnace. Vaporized heated zinc burns in the furnace and oxidizes. The oxidation forms small aerosol particles of the white zinc oxide. The zinc oxide particles, drawn through cooling flues into baghouses or electrostatic precipitators, can then be recovered. Baghouses are buildings containing numerous cloth bags suspended over hoppers. The zinc oxide particles adhere to the cloth material and, after shaking, fall into the hopper for recovery.

American (Wetherhill) Process

The American process uses roasted and sintered zinc concentrates in the production of zinc oxide. The American process has two operational types, a batch and a continuous process. The batch furnace (heated from the base and charged from the top) heats and vaporizes the charge. The zinc oxidizes in the upper portion of the furnace. Withdrawn zinc oxide particles are recovered.

Figure 3.48: American Process Zinc Oxide Production

The continuous process furnace is essentially a moving grate sintering furnace. The charge passes through the combustion chamber and the vaporized zinc oxidizes. Collected zinc oxide is graded and bagged.

Electrothermic Oxide Furnace

The electrothermic oxide furnace operates in the same manner as the electrothermic zinc furnace. The electric current reduces and vaporizes the charge. The vaporized zinc burns in the air.

Waelz Process

Low grade oxide ore, slag from zinc retorts, and slag from lead smelters provide the charge for the rotary kilns in the Waelz process. The kiln processes the charge, producing zinc oxide for collection from the lower end. By controlling the temperature, pairs of kilns can produce both zinc and lead oxides. Keeping the temperature of the first kiln above the boiling point of zinc but below the boiling point of lead produces zinc oxide only. The second kiln, kept above the boiling point of lead, accepts the discharge of the first kiln and yields lead oxides. Operating kilns above the boiling point of both lead and zinc produces leaded zinc oxide.

Figure 3.49: Waelz Zinc Oxide Plant

Figure 3.50: Slag Fuming Plant

Slag Fuming Furnace

Slag from lead smelters provides the raw material for the production of leaded zinc oxides in slag fuming furnaces. The slag fuming furnace is similar to the vertical retort furnace. Heating above the boiling point of lead yields zinc and lead vapors. The oxidized vapor produces leaded zinc oxide.

French Process

Broken slabs of metallic zinc are the charge for the French process. Closed retorts heat the zinc in an atmosphere of carbon monoxide. The vapor burns in the air at the open end of the retort and forms zinc oxide.

By-Products Recovery

Cadmium is the chief accessory metal recovered at zinc plant. Other accessory elements are indium, gallium, and germanium. Sources of the cadmium are roaster and sinterer dust, condenser residue, purification tank precipitates, and zinc sulfate sludge. Three methods recover cadmium, depending upon the source. They are the wet method, the retort method, and the electrolytic method.

The wet method recovers cadmium from roaster and sinterer dust. Leaching and agitating the dust with sulfuric acid forms a slurry. Filtering removes solids leaving a clear electrolytic composed of sulfuric acid and cadmium sulfate. Zinc dust, added to the slurry in lead-lined tanks, precipitates the cadmium. Retorts heat the dried briquetted cadmium past the vapor point of cadmium. Condensers recover the molten cadmium.

The retort method uses cadmium containing material mixed with coke. Heating the retort yields vaporized cadmium for condenser recovery.

The electrolytic method of cadmium recovery is similar to electrolytic zinc processing. Electrolysis recovers metallic cadmium from a cadmium sulfate solution.

Zinc slag and spent electrolytic solution contains recoverable amounts of lead, silver, and gold. Lead smelters recover these metals. A sulfuric acid plant recovers sulfur compounds.

Radioactive Materials

The use of radioactive materials is widespread. Medicine, industry, fabrication, power, and weapon industries use radioactive materials. Radioactive elements (isotopes) exist both naturally and artificially. Examples of naturally radioactive materials are barium, uranium, thorium, radium, bismuth cobalt, cesium, and polonium. The production of artificially radioactive isotopes is by the bombardment of the parent isotope by alpha particles, deuterons, or neutrons (using a chemical or mechanical particle source). Examples of artificial isotopes are iodine, iridium, bismuth, plutonium, xenon, strontium, phosphorus, potassium, gold, cesium, californium, sodium, and yttrium.

The use of radioisotopes in medicine includes diagnosis and treatment of disease, radioactivation and tracer usage, radionuclide imaging, and radiopharmaceutical production. Some industrial uses are in food preservation, polymerization of plastics, analytical testing and measurement, as tracer materials, and the process instrumentation measurements of mass, density, thickness, and moisture content.

The production of radioactive isotopes (with the exception of uranium and plutonium) has no definitive signature. Isotope production occurs by irradiating the parent material in a small non-power production reactor. The neutron flux from the reactor transmutes the parent material into a radioactive daughter. Standard chemical and physical techniques separate the isotopes. These facilities look like any other plant using chemical processing methods. The associated buildings have sophisticated dust and air handling equipment.

Figure 4.1: Uranium Flow Cycle

Uranium Production

The main use for uranium is in power generation. Uranium has limited use in construction of nuclear weapons (nuclear weapon tamping material and as a secondary in H-bombs). Depleted uranium (low in ^{235}U , therefore lower in radioactivity) finds use as weights in industrial applications, armor for military uses, and as solid penetrator elements in conventional weapon design (mostly anti-armor rounds). The three natural isotopes of uranium are ^{238}U (9.28%), ^{235}U (0.71%), and ^{234}U (0.006%). The isotope ^{235}U forms the basis (slow neutron fission) for gun-type atomic weapons (of historical importance only, modern weaponry uses implosion). Modern fission weapons do not require ^{235}U as the primary element. Uranium can form the basis for the secondary fission element in fission-fusion-fission (H-Bomb) devices.

Figure 4.2: In Situ Mining

Natural uranium occurs as oxides (U_3O_8) in association with gold, copper, and phosphate ores. Uranium ores are classified as primary (un-oxidized) and secondary (oxidized) ores. Important primary ores include Uraninite and Coffinite. Important secondary ores include Carnotite and Autunite. Some secondary ores contain phosphates. Traditional mining methods are used to extract most uranium and thorium ores. The most common methods are surface mining through open pit or strip mining or underground mining through vertical shaft or adit.

Figure 4.3: In Situ Leachate Recovery Process

Figure 4.4: Uranium Recovery from Phosphoric Acid (Phosphate Ores)

In situ mining methods can be used in some cases. In situ mining involves blasting the ore into fragments followed by injection by sulfuric acid. The sulfuric acid leaches the uranium, collects in a sump, and is pumped back to the surface. The slurry collects in the shallow rectangular leaching pads. A processing plant then recovers the uranium from the sulfuric acid slurry. One advantage of this method is the prevention of radon gas exposure to the miners. Some mines use leaching methods to recover additional uranium from mine tailings. In addition to uranium mining as the primary ores, some mines producing gold or phosphate ores produce uranium ores as an accessory mineral. In these cases the uranium recovery will occupy only a small portion of the ore processing plant.

The production of uranium metal from oxide ores is an intensive and expensive process. The component plants of the processing chain (for fissionable materials) are geographically dispersed. This prevents the loss of more than one segment in the chain due to catastrophic accident.

Ore Concentration and Treatment

The uranium concentration in the ore is extremely small and large amounts of ore must be processed during recovery operations. Because of the large amounts of ore, the preliminary processing plants are located near the uranium mine. Normal ore concentration methods will not work with uranium ores because of insufficient difference in the physical properties of the constituents. Essentially the entire ore is treated by extraction methods, recovering the uranium. Preliminary treatment of the uranium ore is crushing, grinding, leaching (acid or alkaline leaching), separation, precipitation, thickening, and filtration.

The ore concentration process varies on the type of ore, concentration of the ore, and the age (or sophistication) of the facility. The first step in ore treatment is through primary (jaw or gyratory), secondary (cone), and possibly tertiary (cone) crushers. Next the crushed material is further reduced through grinding (rod and ball mills). The crushed ore can be separated using several methods.

Primary uranium ores are usually separated using leaching, flotation, or a combination of both. Of course, uranium slurry produced from in situ mines will not have associated crushing and grinding sections. The ores will be leached in large open leaching tanks or in pachucas (pressurized vessels) in the concentration building. The ore is treated by an acid or alkaline leach solution. The pachucas treatment is indicated by the lack of roof vents and stains on the concentration

roof. Open tanks will stain the roof through the required roof vents.

Flotation separation occurs in flotation cells located in the concentration building. The flotation cells treat the ore sequentially until no recoverable ore is left. These buildings usually have a stepped appearance. Settling tanks and thickeners remove the concentrates. Next, either solvent extraction or an ion exchange process recovers the uranium from the chemicals used during either of the concentration processes.

An ion exchange method can also be used to purify the uranium slurry. The slurry is neutralized and the solids removed for disposal. The enriched liquid passes through ion exchange units. The ion exchange units consist of an absorption column, a measuring chamber, a rinse chamber, and an elution column. After passing through the ion exchange unit, mixing with lime

Figure 4.5: Uranium Concentration Flow

precipitates iron hydroxide from the liquor. The uranium, mixed with ammonia in thickeners, forms uranium yellow cake, which is then filtered and dried before further processing. Handling of the uranium yellowcake is usually performed by remote control in a separate building. The packaging building is an enclosed isolated structure usually under negative air pressure to maintain adequate control of uranium dust. The material typically is handled under a vacuum to prevent oxidation.

The concentration plant consists of multiple extensive tall single story structures. The storage yard (usually) is stockpiles of metal drums containing both the ore and the finished yellowcake. Uranium storage is in 800-1100 lbs drums. Ore crushing facilities are typical, with the addition of extensive dust handling equipment. Chemical storage tanks, thickeners, separators, and vats are visible. Since the tailings are a health hazard, extra care will be taken in disposal. The tailings are usually disposed into lined pits (ponds) and the filled ponds will be covered with impervious material and fill. Often the concentration plant tailings are re-deposited back into the mine for disposal (when the mine and plant are collocated).

Solvent extraction can be used to recover the concentrated uranium from the reagents used during separation. Sodium chloride, ammonium chloride, or ammonium sulfate are added to the solvent depending upon the impurities co-extracted during the solvent extraction.

Figure 4.6: Basic Concentration Processes

Figure 4.7: Uranium Ore Concentration By Ion Exchange

Feed Materials Plant

Uranium yellowcake (intended for nuclear fuel) undergoes additional processing at the feed materials plant. The feed materials plant converts the yellowcake into metallic or gaseous uranium. Uranium in gaseous state can be sent to enrichment facilities for processing. Metallic uranium can be used in the fabrication of reactor fuel, weapon use, or industrial non-nuclear applications. Reactor fuel material can be in the form of natural (non-enriched) uranium, enriched uranium, or even depleted uranium. Some reactors use a fuel composed of a mixture of uranium and plutonium (breeder reactors that produce additional plutonium).

Wet solvent extraction using ether or fluoride volatility processes are used to refine the yellowcake. In the wet solvent method (conventional processing), uranium yellowcake, mixed with nitric acid and filtered, forms uranyl nitrate. Heating uranyl nitrate (diluted with 50% nitric acid) to 100° C (212° F) in the presence of manganese yields a solid precipitate. Solvent extraction (by ether) produces a pure uranium metal (containing all the isotopes of uranium). At intermediate stages in the processing, the UO_2 may be diverted to produce reactor fuel.

The fluoride volatility process (dry hydrofluor process) produces extremely pure UF_6 . The feed is treated in fluid bed reactors with hydrogen or ammonia to form uranium dioxide (UO_2). The UO_2 is processed in fluidized bed reactors with anhydrous hydrogen fluoride to produce UF_4 . Fluidized bed fluorinators and

Figure 4.8: Feed Materials Production Flow

contact with elemental fluorine and calcium fluoride process the UF_4 into UF_6 . Distillation columns purify the UF_6 . After the fluorination process, the UF_6 is filtered and desublimed in heat exchangers. This causes the formation of solid UF_6 at room temperature and pressure (below 56.5°C [133.7°F]) for temporary storage in large cylinders or tanks. The solid UF_6 is sent to vaporizers and on to distillation columns to allow the production of highly pure UF_6 . The purified UF_6 is stored indefinitely in storage containers (holding around 14 tons) before shipment to the uranium enrichment facilities. The containers are stored in open outside yards and are a critical identification feature of uranium hexafluoride production facilities. The containers are overpacked within a second container for safety during shipment.

Figure 4.9: Wet Solvent Extraction

Figure 4.10: Fluoride Volatility Extraction

Metals Production

Metallic uranium can be produced using fused-salt electrolysis or reactive metals reduction. Natural uranium can be converted directly to the metallic form after shipment from the feed materials plant. Production from enriched or depleted uranium starts with the UF_6 from the enrichment (isotope separation) plant. The gaseous UF_6 is converted to the solid UF_4 by hydrogen contact. This results in the conversion of UF_6 to UF_4 and HF.

The electrolysis process produces a high purity metal. The electrolysis bath is a solution of fused-salt sodium and calcium chloride using a molybdenum cathode. The electric current causes metallic granules of uranium to collect on the cathode. The granules are stripped off, pressed and sintered, or melted into solid metallic uranium.

Most of uranium metal is produced from UF_4 by the reduction process. The refractory charge is UF_4 (green salt) with a calcium or magnesium reducing agent. The dolomitic refractory vessel is heated until an exothermic reaction occurs, melting the charge. The molten uranium metal collects below the slag until solidification and removal. A calcium reducer reacts at room temperature while a magnesium reducer requires preheating. Magnesium and uranium are heated in a "bomb" until the charge ignites. The magnesium method produces higher quality "biscuits" (also called "derby" or "dingot") or uranium masses.

Uranium ingots are commonly prepared from the biscuits by vacuum induction melting. The ingots are machined and handled using conventional metal fabrication methods. The fabrication plants, unless collocated within the nuclear industry, have no particular signature.

Processing facilities for the metal (especially if producing fuel elements) are electric furnaces (housed in tall single story buildings) and nitric acid storage. The finished fissionable uranium metal must be handled carefully to prevent the formation of a critical mass. Critical mass is the amount of material required for fission to occur. For uranium (^{235}U), 8 kg (18 lb) is near critical mass for untamped material, 4.5 kg (9-10 lb) for uranium tamped (surrounded) by a suitable neutron reflector. Critical mass for plutonium (^{239}Pu) is much smaller, around 4.5 kg (10 lbs).

Separation of Uranium Isotopes (Enrichment Processes)

Uranium in the natural state primarily consists of two isotopes. The isotopes are U-238 at 99.3% and U-235 at .7% occurrence. In order to use uranium as a reactor fuel or in weapons applications, the U-235 content must be increased. However, breeder reactors using plutonium and uranium oxide fuels do not require enrichment. The enrichment process is by isotope separation. For example, reactor fuel requires a minimum of 3% U-235 and weapons use requires more than 90% U-235. Uranium greater than 3% U-235 is referred to as SNR (special nuclear material) and that greater than 90% as HEU (highly enriched uranium). Isotopes are chemically identical with only slightly different molecular weights. This makes physical separation a difficult and expensive process.

Gaseous diffusion, centrifugation (including aerodynamic methods), electromagnetic methods, thermal diffusion, electrolytic methods, distillation, chemical-exchange and ion exchange, and laser diffusion can separate the isotopes of uranium. Gaseous diffusion and gaseous centrifuge processes are used in most separation plants. Most enrichment methods require extensive physical plants to operate. Enrichment plants are very large in extent; using enormous amounts of electric power, large amounts of water, cooling facilities, and extensive air purification systems. Most plants are clusters of very large single story buildings connected by a spider-web pattern of insulated pipelines (usually elevated 8 to 10 feet by stanchions).

Gaseous Diffusion

Gaseous diffusion (barrier diffusion) theory is based on the rate of diffusion for elements of different densities (gases). The diffusion rate is inversely proportional to the square root of the density of the material. Lighter gases diffuse faster than heavier gases. By allowing gases to pass through porous membrane barriers (filters) with extremely small holes (1×10^{-5} cm in diameter), successive stages enrich the gas in the amount of the lighter material. The plant is a continuous interconnected cascade (series) of 1000 gallon tanks (with teflon seals) linked by nickel-plated piping. The barrier is a thin metal sheet of electro-deposited nickel, rolled into a tube and placed in the diffusion tank.

Uranium hexafluoride is nearly an ideal gas and is the best compound for separation of the isotopes. Producing the UF_6 gas begins with uranium dioxide (UO_2) metal. Heating the UO_2 to 500°C (932°F) in the presence of hydrofluoric acid

yields UF_4 (uranium tetrafluoride). Uranium tetrachloride and uranium tetrabromide are other, less volatile reaction series for isotope separation. Reacting the UF_4 with fluorine gas at 350°C (662°F) yields the UF_6 (uranium hexafluoride) gas. The UF_6 is a white solid below 60°C (140°F) but in gaseous form is highly corrosive. Alternately, the reaction of UF_4 with oxygen gas at 900°C (1652°F) produces UF_6 .

Calculations for enriching uranium hexafluoride (UF_6) show a maximum enrichment (theoretical) of 1.0043 per stage. Approximately 4000 barrier stages (cascades) are necessary to enrich the uranium.

The continuous process of successive stages requires miles (more than 5 miles) of piping connecting the stages. Separate compressors and coolers are required for each stage, requiring an enormous amount of electric power supplied through numerous electrical substations. Also the diffusion operation requires a vacuum to operate.

The diffusion plant is an extremely large (in area) structure, usually a tall multiple-story steel-frame building. The plant requires a large amount of water and electric power (e.g., electrical requirements are more than 2×10^9 watts/day). There will be numerous substations, possibly a power plant, and a water treatment plant, and dozens of ancillary buildings for laboratories, boiler houses, workshops, security functions, and fire stations. Numerous insulated pipelines are visible as are chemical storage tanks, uranium storage drums, and gas storage

Figure 4.11: Gaseous Diffusion

Figure 4.12: Diffusion Tank Types

cylinders. Exhaust vents and intakes for the processing buildings will have sophisticated filtering systems.

The original K-25 facility is a U-shaped 4 story building with its own thermal power plant and over 100 support buildings. The main structure containing the barriers is 805 m long by 322 m wide (2640 feet long by 1056 feet wide) and has an interior area of $6.1 \times 10^5 \text{ m}^2$ ($2 \times 10^6 \text{ ft}^2$).

Centrifugal Separation

Centrifugal separation consists of introducing the UF_6 gas into a centrifuge. The lighter fluid ($^{235}\text{UF}_6$) accumulates near the axis and the heavier ($^{238}\text{UF}_6$) near the outside edge. Numerous successive series of extremely fast rotation centrifuges (30,000–40,000 rpm) are necessary to produce the required concentration of isotope.

Large scale separation of isotopes requires thousands of centrifuges to process the uranium (40,000–50,000 to produce 1 kg/day) since the centrifuge process is not as efficient as diffusion plants. The original centrifuge chambers are 1.5 meters (4.9 feet) long by .25 meters (.8 foot) in diameter. Newer centrifuges are up to 12 m (40 feet) high. The plant containing the centrifuges is very large with the centrifuge section noticeably taller. Large amounts of electrical power and cooling are necessary to support the operation.

Figure 4.13: Gas Centrifuge

Aerodynamic processes use centrifugal forces delivered at high velocities to effect isotope separation. The UF_6 moves at high speed along a curved surface. The curved deflection surface moves the lighter U-235 easier than the heavier U-238. The U-238 deflects to the outside of the chamber. Again multiple passes through numerous chambers are required to enrich the material. Advantages of these systems are high efficiency and cheaper construction. The disadvantage is the extremely large amounts of electricity required.

Figure 4.14: Becker Nozzle for Aerodynamic Separation

Electromagnetic Separation

Ionized gases (containing isotopes of the same element with identical electric charge) passing through magnetic and electric fields deflect according to their masses. Again a series of successive passes through numerous electromagnets (calutrons) is required to produce the required concentration of UF_6 . The first calutron enriches the isotope by 15%, the second by 90%, and so forth. Several sets of electromagnets, encased in mass spectrometer tanks, are arranged in oval configurations (called racetracks) of 50 feet by 100 feet.

The first electromagnetic separation facility, Y-12, consists of 268 buildings. The calutron building is a tall two-story structure of steel frame, brick, and tile. The racetracks are on the second floor with the first floor housing the vacuum pumps. The plant has numerous labs, shops, warehouses, change buildings, and other support buildings. In addition, the plant has a distilled water plant, a thermal power plant, a sewage treatment plant, pumphouses, a foundry, 8 substations, and 20 large cooling towers.

Figure 4.15: Calutron

Figure 4.16: Plasma Separation

Plasma Separation

A newer process, the Plasma Separation Process, uses a metallic uranium vapor feed of plasma. A solenoid and magnets provide a RF tuned field (to the resonance frequency of U-235) which increase the energy of the U-235. The U-235 moves in a wider spiral orbit that intersects a charged collector plate for recovery. The low energy U-238 passes through the collector plates.

Laser Based Processes

Laser based systems have been developed for smaller, less expensive separation plants. The tuned

Figure 4.17: AVLIS

Figure 4.18: MLIS

lasers selectively ionize U-235 atoms. The laser is tuned to a wavelength that doesn't ionize the U-238 atoms. The U-235 atom absorbs energy, stripping an electron and becoming a positively charged ion of uranium pentafluoride (UF_5). The ions can be attracted to a negatively charged plate for recovery.

The AVLIS (Atomic Vapor Laser Isotope Separation) process uses a feed of vaporized uranium metal and a series of three laser beams for ionization. The MLIS (Molecular Laser Isotope Separation) process uses a feed of UF_6 and helium

gases at 50° K (-223° C [-369° F]). An IR (infra-red) laser provides preliminary excitation and a UV (ultra-violet) laser separates the enriched molecules of UF_5 .

Thermal Diffusion

Introducing a suitable fluid (gas or liquid) into a vertical column equipped with a heating element in the center causes the separation of the isotopes. The heavier isotope concentrates in the cooler outer region of the column while the lighter isotope concentrates in the warmer central area. Then the heavier isotope sinks (due to convection) in the column and the lighter isotope rises.

The original plant is housed in 155 meter (500 foot) long buildings containing the 1 meter to 1.25 meter (3 feet to 4 feet) long

Figure 4.19: Thermal Diffusion

thermal diffusion columns. A cascade of 2,000 thermal diffusion units yields 1 kg/day of 90% uranium isotope. Thermal diffusion plants feed slightly enriched uranium to the calutron plants.

Other

Other chemical and ion exchange methods use ion transfer in aqueous, organic, or resin systems. At present these systems operate at 1/4 the efficiency of other methods and are not viable at large scale.

Figure 4.20: Chemical Exchange Process

Uranium Metal Forming

The isotope separation yields an enriched uranium gas. Once the desired level of enrichment occurs (the typical reactor runs on 93% and naval reactors run on 97% enriched material), a chemical process converts the UF_6 gas to its "green salt" of uranium tetrafluoride (UF_4). Reduction of the UF_4 occurs in a crucible. The UF_4 salt, mixed with biscuits of lithium metal, a reducing agent (calcium or magnesium), briquettes of ^{235}U scrap, and a thermite igniter, burns forming metallic uranium.

Most applications for the uranium metal require the uranium metal foil (.005 inch) layered with graphite moderator. The rolling and stamping mills machining the uranium graphite foils require special vacuum and adhesive techniques.

Plutonium

Plutonium does not occur in nature except in rare minute quantities associated with radioactive decay in uranium. Plutonium forms due to thermal neutron bombardment of ^{238}U and its subsequent beta decay, resulting in the formation of plutonium. Plutonium poses health hazards both because of its radioactivity (all its isotopes are radioactive) and because of its general toxicity (carcinogenic). Plutonium (in the form of ^{239}Pu) is used for nuclear power generation and as the primary explosive constituent in nuclear weapons (fissionable by both slow and fast neutrons). Plutonium (^{238}Pu) also forms the basis for small portable power sources, notably in spacecraft and satellites.

Typical production is by fast breeder reactors. Here ^{238}U fuel (91%) and 9% other isotopes (of ^{239}Pu and ^{241}Pu) transmutes to ^{239}Pu . The neutrons from fission bombard the uranium for 100 days. After a sufficient amount of plutonium is made, the fuel rods are removed from the reactor and allowed to cool (short-lived fission radiation) in cooling ponds at the reactor, this stage requires 60 days. The cooling pond is a bridge crane served lined pool of water. A reprocessing plant recovers the plutonium produced by the reactor.

Typically the reprocessing plant is not collocated with the production reactor. The irradiated fuel rods (slugs) are shipped from the reactor to the plant in heavily shielded and guarded transportation flasks. Storage awaiting reprocessing is in cooling ponds. When ready for processing, the skips containing the slugs are moved into a preparation building where the elements are removed from the rods. The first step occurs in the primary separation plant where the plutonium, uranium, and other elements are separated by chemical processing. The fuel rod material is dissolved in hot nitric acid. The solution is oxidized using cerium or lanthanum fluoride as a carrier. Adding bismuth phosphate as a carrier removes the uranium and other contaminants from the solution. The uranium is recovered as uranyl nitrate hexahydrate.

Evaporation precipitates the plutonium as a fluoride. The plutonium fluoride is re-dissolved in sulfuric acid, re-oxidized and re-precipitated, leaving plutonium. The sequence is repeated numerous times (40-80) before yielding 90% pure plutonium nitrate.

The process is highly radioactive so the structure has heavy shielding and air purification equipment. The recovered uranium is recycled through the uranium isotope separation plant requiring transportation to that facility (if not collocated with the plutonium processing plant). The plutonium purification plant extracts the plutonium and reduces it to metal. Each 907 kg (1 ton) of fuel rods produces 4 kg (1 lb) of plutonium, 862 kg (1900 lbs) of depleted ^{235}U , and 45 kg (100 lbs) of fission by-products (1 kg uranium processing yields 6.0×10^{-7} gram of ^{239}Pu).

The solvents used for the extract process are recycled. The radioactive by-products are graded into highly, medium, or slightly radioactive waste. The low level and medium level waste are stored until the radiation level drops low enough, then the waste is sent to a disposal site. The high level waste requires long term secure storage, usually underground, for thousands of years before disposal.

The original 100B facility plutonium separation plant (canyon building) is a structure approximately 250 meters long by 20 meters wide by 25 meters high (800 feet long by 65 feet wide by 80 feet tall) with 1.8 m (6 feet) thick walls and roof. The building houses 40 sections. Each area has two cells, catch tanks, precipitator, solution tank, and a centrifuge. All the processing is by remote control due to both the toxicity and the radiation danger from the plutonium.

Nuclear Weapons and Fabrication

Fission weapons consist of a plutonium core surrounded by a tamping material such as U-238. Explosive lenses of fast and slow high explosives surround the core. A series of high voltage capacitors (thyristors) provides the split-second timing and charges to detonate the explosives at the critical moment. Upon detonation, the lenses compress the fissionable material to a supercritical stage. Next a (obsolete) chemical initiator such as beryllium-polonium (placed in the center of the core), or a mechanical initiator (such as a minitron high voltage vacuum tube) provides the necessary neutrons to cause a high level nuclear explosion.

An H-bomb uses a fission device as a trigger to initiate fusion in an additional element containing lithium-6 deuteride surrounding more plutonium (another fission chain). The level of the yield (dial-a-yield) may be controlled by injecting

Figure 4.21: Fission Bomb (A-Bomb)

Figure 4.22: Mechanical Initiator

varying amounts of tritium and deuterium gas into the primary before detonation. The neutron bomb is a variation using a casing of tungsten alloy (primarily) with nickel, iron, and rhenium to produce larger amounts of radiation with smaller yield weapons.

The assembly of a nuclear weapon is simple once the fissionable material is processed. However, to protect the considerable investment in physical plants required to produce the components, the processes for fabrication and assembly of nuclear weapons are geographically dispersed. Each step of the process and each component is produced in separate locations throughout the nation. All the components meet at a final assembly plant for final fabrication. This plant will have heavy security, extremely large bunkers for the actual assembly work, and limited completed weapons storage. Typically the same facility handles disassembly of the weapon when its usable life is reached.

Chemicals

Introduction

Chemical industries use chemicals and chemical processes in rearranging raw materials in the production of material. Pressure, heat, other chemicals, and catalysts form the basis of the chemical processing. The general classification of a chemical plant divides plant type into primary chemical production and secondary chemical production. Primary (basic) chemical plants produce a chemical from a basic raw material. A secondary chemical plant produces a finished product from primary chemicals. The third classification, petroleum, produces both primary and secondary chemicals from natural gas and crude oil. Petroleum chemical production is covered under the petroleum and refining section of this book.

Identification of a chemical plant is not difficult, but identification of the actual process may be very difficult. This is especially true in many modern chemical plants where several processes are layered. The size and complexity of plants range from a single small process to very large, multi-process chemical complexes. The components of the plant may be under weather protection, further

Figure 5.1: Chemical Industries Overview

Primary (Basic) Chemical Production

Air Separation

Air separation plants produce the raw materials of nitrogen, oxygen, and argon from the atmosphere. These elements (in liquid or gaseous forms) form the basis for steel, refrigerants, chemical, and missile propellant production.

Figure 5.2: Air Separation Plant Flow Chart

Figure 5.3: Air Separation Plant

The most economical method of producing gases involves compressing atmospheric air using an air compressor after filters remove any impurities. The compressor building is a long, rectangular, flat-roofed structure (one or two story). Gasometers or cold boxes are situated nearby.

Piping transfers the compressed air to a cold box building. Here, heat exchangers cool the air and remove carbon dioxide and water vapor. The processed air goes into an expansion turbine, the air expands, forming nitrogen vapor. A nitrogen column removes the product nitrogen. Compressors re-condense the remaining air into the oxygen column. In the oxygen column, the air moves downward, it becomes richer in oxygen and argon content. At the highest concentration of argon, the argon element is sent to the argon column for impurity removal. The remaining oxygen passes through the oxygen column as the final product. A single cold box is a square structure, taller than the compressor building. Several cold boxes can be located next to the compressor building with all the structures covered by a single long, rectangular, stepped building.

Storage facilities, if any, consist of closed tanks. Wet or dry gasometers are the most common type of tank. When only one tank is present, it serves as a surge tank for excess gas.

Alcohol

An offshoot of the alcoholic beverage industry is the industrial alcohol industry. Medicines, flavoring, and beverages use pure ethyl alcohol (edible alcohol). Additives denature alcohol for industrial use, rendering it in-edible. Uses for denatured ethyl alcohol include the production of acetaldehyde, ethyl acetate, ether, medicinal products, and antifreeze. Butyl alcohol is used in the production of lacquer solvents and esters. The co-products of alcohol production include acetone (solvent) and glycerine (organic chemical synthesis), butylene glycol (butadiene and synthetic rubber production), citric acid (food industry), lactic acid, starches and wheys, and acetic acid (vinegar). Fermentation methods form the basis of the antibiotic and pharmaceutical industry.

Alcohols are produced by fermentation methods or by the petroleum industry (synthetic alcohols). Historically methyl alcohol (methanol) was obtained from the distillation of wood pulp but now is produced by petrochemical rather than fermentation processes. Fermentation processes remain competitive due to the value of the byproducts. In fermentation, microorganisms ferment the starch and sugar in a mash, converting it to alcohol. Distillation purifies and concentrates the solution. Yeast fermentation of an acid mash yields ethyl alcohol (ethanol) and glycerine. Bacteria fermentation of an acid mash yields butyl alcohol (butanol) and the byproduct of acetone and ethyl alcohol.

Figure 5.4: Alcohol Flow Chart

Figure 15c: Naval Vessel Types

Figure 15d: Naval Vessel Types

Figure 37: Military Motor Pool Shop Area

Sometimes vehicles are parked under cover of long, low, open sided parking garages or sheds. Sometimes these sheds are arranged along the sides of the motor pool.

Figure 38: Parking Shed

The motor pool also provides for maintenance and repair of vehicles.

An area will be devoted to this function. This area contains fuel pumps and tanks, wash stands, grease racks and pits, hydraulic lifts, parking garages, and repair shops and garages. Maintenance

Figure 39: Vehicle Checkout and Fueling Area

garages can be identified by a taller roofed structure flanked by smaller structures. The taller structure is a high bay garage, designed to allow the entry of trucks and other tall vehicles.

Missiles

In the simplest definition, rockets are unguided munitions and missiles are guided or steered. Once a rocket motor burns out, the device continues on a course determined by its final velocity. A missile, on the other hand, has at least a minimal guidance system and a method to steer the device. One classification divides missiles into two types. Ballistic missiles, such as ICBMs or SAMs, are

guided by their motors. Non-ballistic missiles, such as cruise missiles, are steered by activating wing surfaces or guidance vanes on the craft.

Strategic rocket forces typically use surface-to-surface ballistic missiles as delivery systems for nuclear, chemical, or biological weapons. Ballistic missiles are classified by their range capability. Intercontinental ballistic missiles (ICBM) have ranges more than 4800 km (3000 mi). Intermediate range ballistic missiles (IRBM) have a range of 1800 – 4800 km (1100 – 3000 mi). Medium range ballistic missiles (MRBM) have a range 1125 – 1800 km (700 – 1100 mi). Short range ballistic missiles (SRBM) are tactical missiles with a range under 1125 km (700 mi). Strategic rockets can be designed for launching from either a fixed site, typically a hardened silo, or from a mobile, usually canister type, launcher.

Cruise missiles are also used for strategic or tactical delivery systems. As with the ballistic missile, the cruise missile can be launched from a fixed site, typically a pad, or from mobile rail launchers.

A variety of tactical support systems have been developed to for use on the tactical battlefield. Some of these systems are missiles and some are rockets. Tactical systems are classified into light-support with a range of 40 km (25 mi), medium-support with a range of 325 km (200 mi), and heavy-support with a range of 800 km (500 mi).

For a fixed launch site, the missile and all its support equipment is always maintained in an operational readiness state. The launch sites are usually hardened silos designed to withstand all but direct hits. As a further precaution, the launch sites are dispersed throughout the area to minimize the damage one enemy warhead could inflict. Most of these silos consist of a small fenced cleared area and concrete silo doors.

Mobile sites typically consist of a pre-surveyed point with geodetic control. In some cases, some site preparation, which may include construction of concrete pads, is done before moving missiles into launch position. Mobile ballistic missiles are not kept in a state of constant readiness. The missile is only fully operational once the missile is erected at the site.

Before continuing with this section, a note about systems and site nomenclature is necessary. A site consists of the missile, the erector-launchers, and all its support equipment. A single missile site, especially when referring to SAMs, may contain several missile launch positions or pads. These launch positions function as a single operational unit. For example, depending on the operational requirements of the system design, a single operational unit SAM site could consist of 8 missiles and eight launch pads. When referring to military missiles, the term multiple refers to the presence of more than one operational unit.

Launch Pad

The large fixed gantry served launch pads are used for the launch of research, intelligence gathering, communications, or surveillance satellites. In other words, these facilities are used for space launch vehicles. These pads are part of large

Figure 40: Launch Pad

Figure 41: Launcher with Mobile Support Vehicles

complexes dedicated to the launch of these devices. The complex is located in a remote area. The complex consists of administration, supply, and control buildings. Numerous checkout, assembly (very large structures), and fuel storage areas serve several launch pads. In addition there will be several electronic areas devoted to communications and guidance functions.

The launch pads are usually surfaced with cement, sand, or earth, since grass and asphalt would be damaged due to the intense heat generated at the time of launch. Around the tall lattice gantry towers will be smaller towers for lights and towers serving as lightning arresters. The simplest launch pad is a round or rectangular surface without any fixed structures. In this case, all the support equipment, the transporter, missile erector, and launcher are mobile.

Surface-to-Surface Ballistic Missiles

Since the size and capabilities of ballistic missiles vary, it is very difficult to determine what missile a particular site supports. Usually larger missiles have longer ranges, carry a larger payload, and can be positioned farther from the perceived threat. Identification of the exact missile relies on ancillary source and the close examination of the missile silo, associated equipment, and deployment characteristics. Refer to the supplemental handbook for additional information on both defensive and offensive missile systems.

There are some general rules for identification of missiles and missile sites. Fixed missile sites are normally located in undeveloped areas, usually close to military bases. The military base provides supply, maintenance, and administrative support for the missile detachments. The necessary elements forming a missile launch facility include missile storage and assembly, launch points, support equipment, propellant and warheads, quarters, security facilities, and transportation.

Missile storage and assembly are performed in one large structure. Typically this structure is an underground or partially buried (bermed) bunker facility. The missile fuselage, motors, and warhead are mated and checked before transport to the silo or launch site.

Figure 42: Types of Silos

The launch points (or firing points) can be pads or silos. The pads can be as simple as 30 – 100 m (100 – 300 ft) diameter round or square concrete paving. Pads will be linked by road or rail to the missile storage area. The launchers (or rails) can be permanently mounted on the pad, or may be part of a mobile system. The missile can also be fired from a silo, an underground facility. The silo remains closed until immediately before missile launch, then blast doors are mechanically opened or blown clear of the tube. There are several silo configurations. Some require the missile to be moved by elevator or track to the firing position. Some execute a "cold launch" of the missile. That is, a steam generator or gas producer exerts sudden pressure against the bottom of the missile, catapulting it into the air for motor ignition. Missile silos are usually fenced with additional electronic detection systems deployed around the area. The silo doors will be visible and in some cases a personnel access door. Most silos maintain a control and launch facility at some distance from a group of silos. The actual silo is un-manned except for security troops.

Figure 43: *Missile Support Equipment*

A variety of support equipment is required for missile launch facilities. Prime movers, transporters, erectors, launchers, and missile silo reload equipment are necessary. Each missile system requires an array of specialized equipment designed for that one missile type.

Most missiles have solid-propellant motors and the propellant is mated to the motor when built. Liquid propellant is rarely used for strategic rocket forces but is still used extensively for space launch rockets and missiles. Liquid propellant requires either a network of pipelines to the launch point or a series of transporters to carry fuel from the storage area to the pad. Rocket fuel is stored like any other explosive material, in widely spaced and bermed tanks or underground facilities. The warheads are stored in distinctive areas with heavy security that includes fencing, towers, patrol roads or paths, and extensive cleared zones around the complex.

Fixed Ballistic Missile Systems

Most are small compact single silos dispersed over wide areas. Individual silos are identified primarily by differences in tone due to access roads, cleared areas for silo doors and access portals, and fence lines.

Major silo based (1991) ICBM systems include Minuteman II/III, Peacekeeper, SS-11 mod 2, & 3, SS-17 mod 3, SS-18 mod 4/5 and 1/3/6, SS-19 mod 3, and SS-24 (rail mobile or silo based).

Figure 44: *Russian ICBM Silo (SS-11, SS-17, SS-18, SS-19 & SS-24)*

Figure 45: Improved Minuteman II/III Silo

Figure 46: Mobile Launcher Types

Photo Interpretation Training Course 364

Mobile Systems

ICBM

Present (1991) mobile ICBM systems consist of the Russian SS-24 and SS-25, mod 1/2. The SS-24 is a rail mobile (also silo-based) system. The SS-25 is launched from a wheeled transporter-erector-launcher (TEL). The requirements for firing a mobile missile include a geodetically controlled and surveyed site.

Mobile systems may be launched from pre-surveyed and prepared positions. Typically the systems are maintained in vehicle (both rail and road) storage sheds until deployment. Then the missile is moved to one of several possible launch sites. In the case of rail mobile systems, the site is a rail siding connected to the main line.

Figure 47: SS-25 ICBM Soft Silo and Mobile TEL

IRBM

Figure 48: SS-24 Rail Mobile Launcher

The major Intermediate Range Ballistic Missile system currently in use is the SS-20 (SABER), which is deployed in soft silos or as fully mobile 12x12 wheeled TEL. The SS-20 is intended for critical theater targets but is slated for destruction under the INF and START reduction treaties. Effective 1991, all SS-20 missiles were to be destroyed. SS-20 bases are presently being re-configured as SS-25 bases.

MRBM

The Pershing 1A (MGM-31) is a SRBM, being replaced by the Pershing II. The Pershing 1 missile is 10.4 m (34.5 ft) long and 1.2 m (3.25 ft) diameter. The system is a fully mobile articulated 8x8 truck and trailer combination TEL that is deployed with a transporter (for generators and testing equipment), a battery control vehicle, and a communications vehicle.

The Pershing II is a MRBM. The missile is 10.5 m (34.5 ft) in length and 1.02 m

Figure 50: SS-20 TEL

(3.25 ft) diameter. The Pershing II uses the MAN 8x8 truck. The Pershing is deployed as a battalion of four batteries of three platoons, each with three TELs per battery.

Tactical Units SRBM (SSM)

There are many tactical surface-to-surface missile systems presently deployed. These systems all fall under the classification of SRBM. Most of the systems are nuclear capable.

The SRBMs include the Lance (MGM-52). The Lance is a fully mobile system mounted one missile per M⁵² tracked TEL (a lightweight wheeled TEL is also deployed). The TEL is accompanied by an M688 tracked loader transporter

Figure 51: Lance SRBM

equipped with two reloads and a missile hoist. The TEL and transporter are 4.87 by 2.69 meters. The missile is 6.2 m (20.25 ft) long and 0.6 m (1 ft 10 in) in diameter.

Pluton

Pluton is a fully mobile system mounting one missile per AMX-30 MBT tracked TEL. The TEL is accompanied by two Berliet support trucks and a Berliet truck-mounted battery control, communications, and intelligence center. The TEL is 6.59 by 3.10 meters. The missile is 7.64 m (25 ft) long and has a diameter of 0.65 m (26 in). Deployment is in regiments. Each regiment has an HQ company, 3 launcher batteries, a transport unit, and a security element of 10 AMX-10P APCs.

Figure 52: Pluton SRBM

Hades

Hades is also a fully mobile system mounted on a 4x4 truck and semi-trailer TEL with one ready missile and one reload. The Hades system is totally self-contained with all equipment carried onboard the one vehicle.

MLRS

A recent development is a modification of the U.S. Multiple Launch Rocket System (MLRS) allowing the deployment and firing of two Army Tactical Missile System (ATACMS) missiles from the MLRS. The ATACMS is a 2 foot diameter maneuvering ballistic missile with a range of 60 miles.

Cultural Areas

Cultural Features 803

Figure 53: MLRS

Figure 54: SS-1e (SCUD-B) TEL

Figure 55: SS-21 TEL

SCUD

SS-1e (SCUD-B/C) is a fully mobile system mounted one per 8x8 wheeled TEL. Deployment is in brigades of 12 – 18 launchers. The liquid fuel four fin missile is 9.5 – 10.4 m (31 – 34 ft) long and .790 – .890 m (31 – 35 in) in diameter. The TEL is 11.5 m (37.6 ft) long and 3.3 m (10.7 ft) wide.

SCARAB

SS-21 (SCARAB) is a fully mobile system mounted one per 6x6 wheeled TEL. The SS-21 is currently replacing the FROG rocket launchers. Deployment is in brigades of 18 launchers. The missile is 6.0 m (19.6 ft) long and has a diameter of 0.85 m (2 ft 10 in).

SCALEBOARD

The SS-22 (SCALEBOARD) is a fully mobile Short Range Ballistic Missile, mounted on an 8x8 wheeled TEL. The SS-22 replaced the SS-12 missile and launcher that was identical in appearance to the newer SS-22. This system differs in appearance from the SCUD-B Surface to Surface Missile only in the protective environmental cover over the SS-22 missile. Deployment is brigades of 12 – 18 launchers.

Figure 56: SS-22 (SCALEBOARD) TEL

Figure 58: SS-23

SPIDER

SS-23 (SPIDER) is a fully mobile system mounted one per 8x8 wheeled TEL. This system is the planned replacement for the SS-1 in the Russian inventory.

Figure 57: SS-23B TEL

Surface-to-Air Anti-Ballistic-Missile (ABM)

ABM systems are designed for the point defense of very high priority targets. Such targets normally are restricted to the National Command Authority, capital cities, or the military command structure. Presently there exist three true ABM systems, the Soviet ABM-1, -2, and -3. Three other systems offer some ABM capabilities. These are the Soviet SA-10 and SA-12 and the U.S. MIM-104. An ABM system is a complex network of missile launchers, engagement and tracking radars, and early warning radar and communication systems.

For example to support the ABM-1 system around Moscow, 11 HEN HOUSE detection and tracking radars sited at six locations around the perimeter of the Soviet Union provide target-tracking information. Besides the large phased-array radars, the Russians maintain 7,000 radar systems at 1,200 sites to provide medium to high altitude coverage throughout the country.

Figure 60: Pushkino ABM Radar

GALOSH

The ABM-1 (GALOSH) is a fixed ABM system only deployed around Moscow. Each multi-stage exo-atmospheric interceptor is housed and launched from gimbal-mounted cylindrical single-missile launchers. Sixty-four (64) missiles are deployed at four launch complexes. Each launch complex has six TRY ADD guidance and engagement control radars. The four complexes are jointly served by DOG HOUSE and CAT HOUSE target tracking radar. Additional radar support is provided by the Pushkino phased array early warning and tracking systems, PILLBOX radar. The missile is 18 – 19 m (59 – 62 ft) long and 2.4 – 2.7 m (95 – 106 in) in diameter.

GORGON

The ABM-2 GORGON is a silo launched high altitude long range missile. The GORGON (SH-04) is an exo-atmospheric missile that probably has anti-satellite capabilities. The GORGON is the GALOSH replacement. With the completion of the update, 100 ABM launchers will circle Moscow.

Figure 61: ABM-1B

GAZELLE

The ABM-3 GAZELLE is a silo launched high acceleration endo-atmospheric missile. This missile is designed to intercept targets missed by the GORGON or as a point tactical missile defense.

GRUMBLE

Several surface-to-air systems also perform ABM roles. A full discussion of these systems will be found in the following chapter on surface-to-air missiles. These systems include the SA-10 (GRUMBLE), an air defense system consisting of fully mobile wheeled vehicles. The system can operate as point defense against ballistic missiles. The TEL carries four missiles housed in circular canisters arranged in a square. A battery consists of eight TELs, a 3-D surveillance radar, and a search and acquisition radar, all mounted on 8x8 trucks.

GLADIATOR & GIANT

The SA-12 systems can engage SRBM and cruise missile targets. The SA-12A (GLADIATOR) and SA-12B (GIANT) air defense system is a fully mobile track-mounted system. SA-12A missiles are carried four to

a TEL, in a linear array of circular canisters. Each TEL has an integral guidance radar (mast) at the front of the TEL. A battery consists of six TELs, six launch and reload vehicles, one phased array missile guidance radar, and command vehicles. The battle unit, composed of four batteries, provides a detection/designation station, Command Post vehicle, panoramic surveillance radar, and a sector scanning radar. All are mounted on tracks.

PATRIOT

The MIM-104 (PATRIOT) system has limited anti-missile capabilities. The original system, Theater High Altitude Area Defense (THAAD) was an anti-tactical ballistic missile (ATBM) with full anti-missile capabilities. However, to comply with SALT treaties, the software has been purposely degraded to preclude use against ballistic warheads and missiles. The Patriot (MIM-104) is a fully mobile wheeled system. Each TEL carries four missiles in rectangular canisters arranged in a square. The TEL has a small radio mast at rear of the vehicle. Each battery consists of eight TELs, one AN/MPQ-53 phased array radar (surveillance, IFF, acquisition, target tracking, and guidance functions), one AN/MSQ-104 engagement control station, and one AN/MJQ-24 electric power plant. A battalion will consist of six batteries.

Surface-to-Air Missiles (Anti-Aircraft)

Anti-aircraft systems include both anti-aircraft artillery (AAA) and surface-to-air missiles (SAM). Since AAA and SAMs perform the same function, the location and configuration are similar. AAA and SAMs protect critical targets from attack from aircraft, cruise missiles, and ballistic missiles. Each system has a design envelope limiting the type and speed of possible targets and the maximum range and altitude for engagement. This design mandates both the location of the battery and the configuration of the weapons and support elements. Often AAA is sited to provide additional protection for the SAM batteries from air assault.

The SAM employment is influenced by two concepts, point or area defense. Point defense is protection of a specific target. The target can be a particular industrial or military complex, or an entire city. Point defense sites are

Figure 62: Typical SAM

Figure 63: Typical SAM Site

normally clustered in concentric circles around the defended target. Point defense SAMs are often short range and include most mobile tactical systems. Area defense is the interception of attackers at a distance remote from targets. The line of SAMs is located away from the targets being defended. Area defense missiles include long range and high altitude strategic fixed systems. Area defense systems are sited to provide overlapping protection. Point defense systems may be incorporated within the area defense systems to protect these systems from attack.

SAM systems are composed of several identifiable elements that include the launch site, the acquisition radar and guidance site, and the assembly site. The assembly point is where the missile is received, stored, and checked out. This is usually a sheltered building or underground bunker. The type and quantity of associated equipment vary with the missile system. Some typical equipment includes missile storage and shipping canisters, missile transporters, cranes, support trucks, and checkout vans. For strategic missiles, the site is usually central to several missile launch sites. Tactical mobile units carry all the required equipment in associated vehicles.

The radar acquisition site may be separate from the missile launch site. Acquisition radar keeps track of possible targets and target information such as number, speed, altitude, and range of enemy planes or missiles. The information is sent to the missile launch site. Acquisition sites receive information from long range or early warning radars. This allows for a directed search for targets. Guidance sites may be incorporated within the missile launch site. The guidance site provides the particular type of information and control the system needs to intercept the target using various radar and radio control and direction methods. Possible modes include command, beam-riding, or semi-active homing.

Launch sites contain the missiles, launchers, and the necessary support equipment. The site varies with the system and mobility type.

AntiAircraft Artillery (AAA)

All AAA is emplaced to provide the guns with a clear field of fire against a line of restricted approach. Emplaced guns are arranged in pattern outlines from groups of guns. The battery is usually not camouflaged because of the requirement for unobstructed field of fire and quick gun tracking. Most light AAA has integral fire control radar. Heavier weapons may have a separate and external fire control radar and fire control.

Antiaircraft machine guns (AAMG) and light antiaircraft artillery (LAA) are light-weight and extremely mobile. They may be sited on top of buildings, towers, or on high ground. The lighter weapons are sometimes located within the actual target area. This caliber of weapon is used in defense against high speed low altitude aircraft. Entrenched emplacement is not always used. The AAMG (less than 20 mm) may be laid out in irregular patterns, clusters, straight lines (most common), or box patterns of 4-guns. Emplacement size for the AAMG is 1.2 – 3.7 m (4 – 12 ft). LAA (20 – 75 mm) are commonly laid out in 4 or 6 gun patterns, within emplacements of 4 – 6 m (13 – 20 ft) diameter.

Medium anti-aircraft artillery (MAA) can engage targets at medium to high altitudes. The MAA will be located in road accessible open areas (fields). The MAA is located within several thousand meters of the target area. MAA (76 – 100 mm) batteries are deployed in groups of 4, 6, or 8 guns. The 5 – 8 m (16 – 26 ft) diameter revetments are typically in box, circle, semicircle, trapezoid, straight line, or staggered line patterns.

Heavy anti-aircraft artillery (HAA) engages high altitude targets. The HAA (>101 mm) is deployed in the same manner as the MAA. The revetment size is more than 8 m (26 ft) in diameter. The pattern of revetments is similar to MAA, guns are usually in groups of 4 or 8 (rarely 6 or 12) guns.

Fixed Systems

Fixed systems are all those SAMs that are non-mobile or have limited mobility. These SAMs are sometimes referred to as strategic defensive missiles since they protect large or vital fixed targets of national importance. Some of these systems have limited mobility in the sense that they can be relocated. But the relocation is difficult and time consuming. Several major strategic systems will be discussed, however, the list only includes NATO or former USSR systems. Some systems have been developed by Communist China, North Korea, and several additional countries. Many of these missile systems are copies or modifications of NATO and Soviet design.

No matter which system is deployed, fixed strategic SAM sites have several features in common. The site has a ready missile storage area containing sufficient missiles for several engagements. The storage may be located near the launch points when rapid reloading facilities are present. Typical storage is in under-

Figure 64: Strategic SAM Systems

ground bunkers or bermed buildings. Bulk fuel (liquid) storage will be located some distance from the complex and pipelines will link the bulk fuel facilities to launchers or revetted fuel transfer areas. Almost all modern systems use solid fuel motors and fuel will not require separate storage. Typically the solid fuel motor will be mated with the missile at the assembly point.

Launch, or firing, points consist of revetted circular or rectangular pads. The pads may be surfaced or consist of graded and rolled earth. Surface launchers (permanently fixed) consist of either rails or tables. Underground sites maintain large steel doors through which the launcher is raised for firing. The number and configuration of launch points are dependent on the missile system. The system used is partially dependent on the required reload rate and number of expected targets per engagement. Rails, elevators, trolleys, and other specialized devices transport ready missile reloads to the launcher.

Support equipment will consist of mobile missile transporters and cranes. Virtually every strategic site has a very well developed and well maintained road network linking the complex elements. The entire complex will be protected by security fencing or walls. Radar and radio guidance, tracking, control, and early warning equipment will be visible. This equipment may be centrally located or maintained in a separate location some distance from the actual launch pads.

BLOODHOUND

The Mk 2 Bloodhound is a strategic defensive nuclear capable system deployed in the UK only. The 7.75 m (25.5 ft) radar guided (illumination) surface-to-air missile is deployed as four fixed single rail launchers per battery. The system includes a mast mounted target illumination radar, search and acquisition radar, and a battery control center. The missile has a range of 80 km.

NIKE-HERCULES

The NATO NIKE-HERCULES (MIM-14B) is a long range (160 km) medium to high altitude command guided nuclear capable strategic defense system using a 2 stage 12.7 m (42 ft) long missile.

Nike-Hercules (MIM-14B) may be a relocatable site or a fixed site. Fixed sites consist of a launch area and a guidance site. Launch sites are hard surfaced launch positions with three single missile launchers, three launch positions

Figure 65: Nike-Hercules Launch Site (In-Line)

per area. The guidance site will be within 5 NM of the launch site within line of sight of the missiles. The battery control center, radar and radar test mast will be located here.

Launch site configuration may be in-line, L, or triangular. Each of three launch sites will have launchers, launch control building, maintenance and ready missile storage, and generator buildings (or vans). There is separate warhead mating building and a launch control group van. At the rear of each launch area is a large peak-roofed maintenance and missile ready storage building that services the three launchers. Each launch site has concrete earth covered control bunker, at the side.

Administration and security buildings are near the entrance to the site. The launch control van is located near the administration area. The warhead mating building is located on a loop road situated between the administration area and the launch area.

The guidance area has a generator, battery control center building, and a radar test mast (test mast is 150 m (500 ft) distant from the battery control center (BCC) and will be to the rear). Radars are in-line and consist of a target tracking radar, a target ranging radar, a missile tracking radar, a low-powered acquisition radar, and a high-powered acquisition radar.

Figure 66: Nike-Hercules Guidance Site

SA-1

The SA-1 (GUILD) Soviet medium altitude missile is 12 m (39 ft) long and has a diameter of 0.70 m (27.6 in) with a range of 50 km. This almost obsolete missile is deployed at only three locations within Russia. The launcher is a modified V-2 (German A-4) table. The system launches from a vertical position. Guidance and radio command are by Yo-Yo radar.

SA-2

The fixed or semi-mobile (relocatable) missile is 11.3 m (37 ft) long and a diameter of 0.6 m (2 ft) with a range of 50 km. Soviet designation for the SA-2 (GUIDELINE) is S-75. This is a medium level surface-to-air missile is fired from fixed single-rail launchers. A battery consists of six launchers. Tracking and guidance is by FAN SONG (fire control) and SPOON REST (target acquisition) radars. The missiles are transported by a ZIL-157 truck tractor and semi-trailer. Transporter overall length is 14.5 m (47.5 ft) and width is 2.3 m (7.5 ft).

Figure 6.3.67: SA-2 (GUIDELINE) launcher

Figure 68: SA-2 (GUIDELINE) on Transporter

Figure 69: SA-2 Site Configuration

SA-3

The 2 stage solid fuel missile is 6.2 m (20.3 ft) long and has a diameter of 0.3 m (1 ft). The SA-3b (GOA) is a medium to low altitude system with a range of 20 km. Soviet designation for the SA-3 is S-125. The fixed non-mobile sites are deployed as batteries of four launchers, with each launcher holding two or four missiles. Radars include FLAT FACE (van mounted target acquisition), LOW BLOW (fire control) and SQUAT EYE (target acquisition) systems. Missiles are transported two per truck on a ZIL-157.

SA-5

This medium to high altitude long range (300 km) system is used for national air defense and is deployed only within the borders of Russia, former Soviet republics, and select client states, notably in the Arab states. Soviet designation for the nuclear capable SA-5 (GAMMON) is S-200. The missile is 10 m (33 ft) long and 0.875 m (34 in) in diameter. The SA-5 (GAMMON) surface-to-air missiles are deployed in batteries of six launchers. Radar is SQUARE PAIR.

Figure 70: SA-3 (GOA) Launcher and Transporter

Mobile Systems

Although the operational concept of mobile and fixed systems are the same, there are some differences in the facilities. All fully mobile SAM systems have solid fuel motors. There is no requirement for fuel trucks, refueling points, or bulk fuel storage. Guidance and control systems are deployed in mobile vans and trailers. Support equipment is specialized missile transporters, maintenance vans, and security elements (using standard military vehicles). The firing points vary from any suitable cleared area for the fully mobile tactical units to revetted emplacements with a road network for units expecting long term deployment.

Figure 71: Integrated Communications Network (Patriot)

Figure 72: SAM Operations (HAWK)

An integrated air defense network not only is required to protect one area of operations, but is required to defend a large area. For this reason, numerous SAM batteries have to coordinate communications and operations. Each SAM unit has several communication and control channels available.

CHAPARRAL

The CHAPARRAL (MIM-72/MIM-72 C/F) is a low altitude, short-range, surface-to-air missile. The command to line-of-sight system uses a modified IR seeker derived from the Sidewinder AIM-9D. The 2.87m long missile has a range of 17.7 km, a speed of MACH 2.5, and an altitude limit of 6.1 km. Target acquisition is visual or radar with IR missile homing.

Figure 73: CHAPARRAL

Figure 74: CROTALE

The fully mobile TEL is a tracked M730 carrying 4 ready to fire missiles in rotating turret and 12 reloads. The acquisition vehicle is a M561 Gamma Goat 6x6 truck carrying an AN/MPQ-49 surveillance radar. Normal U.S.A. deployment is in air defense battalions of 2 Chaparral batteries (total 24 launchers) and 2 M-167 (self-propelled Vulcan 20mm AAA). Each launcher unit operates independently and there is no set battery configuration.

CROTALE

The CROTALE is a short range, low altitude, all weather, surface-to-air missile. The command to line of sight MACH 2.3 missile has a range of 10 km operating at altitudes of 15 m – 4 km. Also known as the CACTUS Air Defense System the missile is 2.89 m in length.

The fully mobile system is based on the P4R 4x4 truck. Deployed as one acquisition unit, three TELs, and reload units. The acquisition unit carries the acquisition radar. The TEL carries tracking radar for missile tracking and guidance, and four R440 missiles in tubular launchers. The reload unit is a truck with a crane. Before the 4000 series, units were connected by landline cabling with a maximum

Figure 75: Field Deployment for CROTALE

separation of 800 m. Series 4000 and later have radio linkage permitting separation of 2 kilometers between system components. Series 5000 permits the addition of four short range, point defense missiles to be added to the exterior of two of the R440 canisters for saturation defenses. The trucks are 6.22 by 2.65 m.

The CROTALE is field deployed in a line formation of three TELs with the acquisition radar a maximum of 500 m from the farthest TEL. An alternative formation is a triangular arrangement with the radar occupying the center position.

The SAHV-3 is a replacement system for CROTALE consisting of a new turret and upgraded missile using the standard CROTALE chassis.

HAWK

The NATO HAWK (MIM-23) or I-HAWK (MIM-23B) is a mobile system using semi-active radar homing. The missile is 5.03 m in length with a range of 40 km at 2.5 MACH with operational ceiling of 15 m – 16.5 km.

Deployment is in 2 launch areas with three 3-rail launchers and a continuous wave illumination radar (CWILL) in each area. (Normal deployment of the HAWK is 6 launchers per battery. For the I-HAWK, deployment is 9 launchers per battery [TRIAD].) Both areas share a pulsed acquisition radar (PAR), a continuous wave acquisition radar (CWAR), a range only radar (ROR), an AN/TSW-8 battery control center (BCC), an AN/MSW-11 Platoon Command Post, and a communications area (AN/MSQ-95 Information Coordination Central van).

There is 1 AN/MPQ-50 PAR per battery for volume search of targets. Each battery uses 2 AN/MPQ-48 CWAR (3 in TRIAD battery) for low altitude search. One AN/MPQ-51 ROR is a J-Band unit used to defeat ECM. The AN/MPQ-46 CWILL provides missile guidance, there are 2 in standard batteries and 3 in TRIAD batteries.

PREFACE

In 1975, the U.S. Geological Survey initiated production of land use and land cover and associated maps for the United States. Documenting the land use categories shown on the maps and providing insight into the environmental effects of land use have been long-standing user requirements. This USGS publication illustrates the various land use categories in order to provide the user with a means of interpreting these categories from aerial photographs. Comments on potential environmental impacts are included.

Geographic areas to be used for this publication were reviewed in depth. Missouri was selected because land use and land cover map compilation for that area was complete. We reviewed and considered several well-known and respected thematic maps in an attempt to identify meaningful regions in the State which would be viewed as a framework for developing land use and land cover category documentation. Among these maps were Kuchler's Potential Natural Vegetation map of the United States, Lobeck's Physiographic Provinces, Fenneman's Physical Divisions, and Hammond's Classes of Land Surface Form in the Forty-Eight States. While all of these maps portray basically similar themes, each addresses only a specific characteristic relating to the surface of the land. None of the maps provides a logical framework for all the land use and land cover categories. Accordingly, it was decided to use the USGS Land Use and Land Cover maps of Missouri to select the locations of specific land use and land cover patterns illustrated in this publication.

LAND USE/LAND COVER AND ENVIRONMENTAL PHOTOINTERPRETATION KEYS

By George L. Loelkes, Jr.¹, Gordon E. Howard, Jr.², Eddie L. Schwertz, Jr.¹,
Phillip D. Lampert¹, and Stephan W. Miller¹

ABSTRACT

The preparation of land use maps requires a basic understanding of photointerpretation principles, land use taxonomy, and the proper use of mapping specifications. Each of these topics is developed in sufficient detail to ensure that the reader is exposed to these basics. Since the use of the land can present different environmental impacts, the potentials for environmental degradation are analyzed. Perhaps the most difficult tasks involved in land use mapping is recognition of the different land use types. Aerial and ground photographs, when combined with narrative descriptions, can provide a ready reference for the photointerpreter. Over 230 illustrations and narrative descriptions meet this need.

SECTION 1: INTRODUCTION

This publication has been jointly prepared by the U.S. Geological Survey and the Environmental Protection Agency (EPA) as a means of disseminating information on the U.S. Geological Survey land use and land cover mapping effort and the potential effects of land use on the environment. Primarily, the guide is intended for use by land resource and

environmental planners and managers who utilize land use and land cover maps in decisionmaking.

This guide serves as a learning tool for the use of remote sensing technology and land use and land cover classification and mapping, (table 1-1), as well as an environmental guide and photointerpretation key to help users better understand the photographic recognition features of the various land use and land cover categories. It documents the existence of various Missouri land use and land cover categories as they are portrayed on the maps produced by the U.S. Geological Survey. Finally, it provides a set of environmental keys which can be correlated with various land use and land cover categories and patterns (figure 1-1).

The guide is designed to demonstrate the applicability of land use and environmental keys; to develop data acquisition techniques for compilation of the keys; and to indicate the potential effects of various land uses on the environment.

Ultimately, it may be possible to produce a series of regionally oriented guides to provide land use and land cover and environmental keys for the United States.

The State of Missouri was chosen for the first guide for several reasons. Missouri contains a variety of topographic forms, vegetative cover, agricultural practices, and urban areas of various sizes and patterns. Second, the land use and land cover and associated maps of the State of Missouri had been completed. Finally, since the authors work in Missouri, the cost of acquiring photographs and field data could be kept to a minimum.

Figure 1-1.--Photointerpretation keys--site locations.

SECTION 2: REMOTE SENSING FOR LAND USE INTERPRETATION

What is Remote Sensing?

Remote sensing can be defined as the acquisition of information by a detection device that is not in physical contact with the object or phenomenon under study. Remote sensors for land analysis are of two major types: photographic and nonphotographic.

Photographic sensors produce an image directly on a film emulsion from reflected electromagnetic radiation of wave lengths in the visible and near-infrared portions of the electromagnetic spectrum. The common camera is the best-known photographic sensor.

In comparison, nonphotographic sensor images are captured by a suitable detector and stored as electronic impulses by a recording device. Nonphotographic sensors operate in the ultraviolet, visible, infrared, and microwave portions of the electromagnetic spectrum.

Nonphotographic sensors can be further classified as passive or active. Nonphotographic, passive remote sensing systems detect energy emitted or reflected as radiation from a given scene. The system produces, transmits, and records no energy of its own. Two of the most frequently used nonphotographic, passive remote sensing systems are multispectral scanners, such as those on board the Landsat satellites, and the thermal infrared scanners used to detect temperature contrasts in water bodies, forest fires, and home insulation efficiency analyses (thermograms).

Nonphotographic, active remote sensing systems transmit their own electromagnetic signals at objects and then record the energy reflected or refracted back to the sensor. Radar remote sensing devices are the most commonly used nonphotographic active remote sensors. Radar sensors are particularly well suited for imaging landscapes obscured by clouds.

The illustrations used in section 6 were obtained with conventional photographic cameras. The reader should refer to available textbooks on remote sensing or photogrammetry for more specific information or details on photographic or nonphotographic sensors (see "Selected References").

Resolution

Resolution refers to the minimum separation between two objects at which the objects appear distinct and separate on an image. The

greater the ability of the remote sensor system to distinguish separate objects, the greater the image resolution. Image quality is a function of the remote sensor system's component resolving powers. The combined effect of the system components, such as camera focal length, shutter speed, film type, and sensor altitude (together with other factors such as Earth curvature or atmospheric haze), contributes to the overall resolution of the image.

Although the term "resolution" is used to describe the capabilities of photographic sensors to produce sharply defined images, it is also used to refer to the capabilities of nonphotographic sensor systems to produce sharply defined images. However, unlike photographic sensor systems in which resolution is expressed as line pairs per millimeter, nonphotographic sensor resolutions are expressed in a variety of ways (see Reeves, 1975).

The theoretical maximum resolution of a sensor system is rarely achieved in actual operation. Although resolution is admittedly an important aspect in mission planning, one should remember that resolution is the minimum separation between two objects for which the images appear distinct and separate; it is not the size of the smallest object that can be seen on an image. With the knowledge of the smallest objects that will have to be identified and their spacing characteristics, one can plan a mission (Sabins, 1978, p. 22-25).

Although most planners and natural resource agency personnel believe that scale is the most important factor in producing thematic map products, it should be noted that remote sensor system resolution is usually more critical than the original photographic or nonphotographic scale. The scale of an image can be enlarged or reduced; however, nothing can be done to increase the degree of detail captured as a function of the remote sensor system resolution once the mission has been completed.

Scale

Scale refers to the mathematical relationship between a distance on an image and the corresponding distance on the Earth. The larger the scale, the closer the image size is to the actual size of the object. For example, a scale ratio of 1 inch on the photograph equals 1 inch on the Earth means that an exact one-to-one relationship exists. This relationship can be expressed as a ratio

with a colon (1:1) or as a representative fraction, with the numerator referring to the measurement on the photograph and the denominator referring to the measurement on the Earth's surface. When referring to scale, it is important to remember that the relationship expressed is a ratio. Therefore, it does not matter whether one uses inches, miles, or any other unit of measurement; only that the same units be used for both the image and its corresponding distance on the Earth's surface.

Camera scale is also the ratio of the focal length of the camera to elevation of the camera above the terrain being photographed. Mathematically, the scale is calculated as follows:

$$\text{Scale} = \frac{H-h}{f}$$

H = aircraft altitude above mean sea level

h = mean ground elevation

f = focal length

For example, suppose an aircraft is flying at an altitude of 22,000 feet above mean sea level (msl), with a 6-inch (0.5 foot) focal length camera, over an area with a mean ground elevation of 2,000 feet. Inserting these values into the above equation yields the following results. Accordingly, the scale of this photograph is 1/40,000.

Scale =

$$\frac{(22,000 \text{ ft.} - 2,000 \text{ ft.})}{0.5 \text{ ft.}} = \frac{20,000}{0.5} = 40,000$$

It should be noted that different focal lengths or different altitudes of the aircraft will result in different photographic scales. For example, if the camera focal length in the preceding example were increased to 12 inches, the scale would become 1:20,000. Suppose it was necessary to obtain the larger scale photographs but a 12-inch focal length camera was not available. The larger scale photographs could be obtained using a 6-inch focal length camera by reducing the flying altitude to 12,000 feet msl. However, every time the scale is increased by a factor of two, four times as many photographs are required to cover the same area.

Remote Sensing Platforms

The term "remote sensing platform" refers to objects, structures, or vehicles upon which

remote sensing devices are mounted. Remote sensing platforms can range from truck booms, to aircraft, to Earth-orbiting satellites. The decision to use a particular platform is primarily a function of the altitude, stability, and temporal requirements for a specific remote sensing project.

Although there are three main categories of remote sensing platforms--ground-based, aircraft, and spacecraft--only aircraft and spacecraft will be addressed in this section.

Even though it is quite common to have both photographic and nonphotographic sensors (such as multispectral scanners, thermal scanners, and radar) mounted on aircraft, photographic sensors are carried on board spacecraft to a far less extent than on aircraft. Some notable exceptions include cameras which were carried into space on board Apollo flights, Skylab, and the Space Shuttle.

The list of specific types of aircraft and spacecraft platforms is very long. The reader should refer to the Manual of Remote Sensing (Reeves, 1975, pp. 539-588) for descriptions of these platforms.

Photographic images are classified according to platform type as either aerial photographs or satellite photographs. Aerial photographs can be further categorized as low-, medium-, or high-altitude photographs. Although the specific values for each of the three ranges differ from user to user, a practical method of altitude classification takes into consideration aircraft operational characteristics and the suitability of the final photographs for topographic and/or planimetric mapping.

Most fixed-wing propeller-driven aircraft operate below 24,000 feet msl. Aerial photographs acquired below 24,000 feet msl will generally have a medium to large photographic scale. Photographs obtained below this altitude can be classified as low-altitude aerial photographs. Photographs acquired above 24,000 ft. msl will have a medium to small photographic scale and are most often classified as high-altitude photographs.

Photographs of the Earth have been taken on the Gemini, Apollo, and Skylab missions. For example, Skylab was placed in orbit about 270 miles (435 km) above the Earth. On board Skylab was a six-lens multispectral camera system with a 6-inch focal length and an Earth terrain camera system with an 18-inch focal length. Both of the camera systems were used extensively to test different film/filter combinations from space.

Nonphotographic remote sensors have been mounted on a variety of aircraft and spacecraft platforms. Since this guide is

aimed toward the use of conventional aerial photography and its interpretation, the topic of nonphotographic remote sensors will not be covered in depth. In addition to the photographic sensors onboard Skylab, five nonphotographic sensors were operated: an infrared spectrometer, a multispectral scanner, a microwave-scatterometer, an altimeter, and an L-band radiometer.

Landsats 1, 2, and 3 have been equipped with a return beam vidicon (RBV) television camera and multispectral scanning (MSS) system.

Figures 2-1, 2-2, 2-3, and 2-4 illustrate scale and ground resolution differences from four different remote sensor platforms.² Figure 2-1 is an MSS band 5 image from Landsat 1 taken from approximately 570 miles (918 km)--ground resolution approximately 200-250 m, approximate scale 1:1,000,000 (Sabins, 1978, p. 69). Figure 2-2 is a black-and-white reproduction of a color-infrared (CIR) satellite photograph obtained from Skylab 2 at approximately 270 miles (435 km) with an 18-inch focal length camera--ground resolution 30-40 m, approximate scale 1:950,000. Figure 2-3 is a black-and-white reproduction of a high-altitude CIR photograph taken from approximately 65,000 feet msl with a 6-inch focal length camera--ground resolution 4-5 m, approximate scale 1:130,000. Finally, figure 2-4 is a black-and-white USGS aerial photograph taken from an altitude of approximately 15,000 feet

Figure 2-1.--Portion of a Landsat 1 MSS Band 5 image of St. Louis, Mo., (near center of image) October 20, 1972, (approximate scale: 1:1,000,000).

²Ground resolution refers to the smallest object size or distance on the ground which can be identified. As a "rule-of-thumb," ground resolution is four times the overall system resolution (detection resolution).

Figure 2-2.--Black-and-white reproduction of a portion of a Skylab 2 color-infrared satellite photograph of St. Louis, Mo., (top-center of photograph) September 6, 1973 (approximate scale: 1:950,000).

Figure 2-3.--Black-and-white reproduction of a portion of a NASA high-altitude, color-infrared photograph of St. Louis, Mo., October 9, 1974, (approximate scale: 1:130,000).

msl with a 6-inch focal length camera--ground resolution 1-2 m, approximate scale 1:30,000.

Note that as the remote sensor altitude decreases, the photographic resolution increases, and the ground resolution (the smallest recognizable object size) increases.

At present, detailed land use mapping relies most heavily on high-resolution aerial photographs. Satellite photographs and spacecraft multispectral scanner images, for

Figure 2-4.--Portion of a black-and-white vertical mapping photograph of downtown St. Louis, Mo., July 30, 1974, (approximate scale: 1:30,000).

example, Landsat images, are used for more generalized land cover mapping (see table 1-1, Level I categories).

As explained in the following section, the primary photographic data source for the USGS national Land Use and Land Cover Level II mapping program is either NASA "U-2" high-altitude color-infrared (1:120,000- to 1:130,000-scale) photographs or 1:80,000-scale black-and-white USGS quad-centered photographs.

Aerial Film Types

Photographic film consists of a cellulose acetate or polyester base coated on one side with a light-sensitive layer (the emulsion) and on the other side, with an antihalation backing--a light-absorbing coating which prevents backscatter of the photographic image beyond its proper boundaries. Silver halide crystals suspended in a gelatin are the main active ingredients in the film emulsion.

During the time that the camera shutter is open, light strikes the emulsion and the image of the scene is recorded on the film as a reversed, or negative, image. The amount of light reaching the film base determines the film density (opaqueness) for any specific area of the film. The greater the amount of light reflected from an object, the more dense the film's area for that object. When positive images are printed from the negative film, the dense areas of the negative hold back light and produce light tones on the print, whereas the less dense areas allow more

light to be transmitted to produce darker tones on the print.

The resolving power of the film affects the final resolution of the photograph. Among the factors that affect the film resolution is the size of the silver halide crystals or grains, which determines the exposure time required for correct density and contrast. Earlier, it was noted that the amount of light reaching the film base determines the film density for any specific area of the film. As the size of the silver halide crystals in the emulsion increases, the amount of light required to produce the correct density and contrast decreases. A fast film having rather large silver halide crystals in its emulsion layer requires a short exposure time. However, the large silver halide crystals reduce the film's ability to produce sharp images (film definition) and therefore reduce resolution.

The motion, particularly forward speed, of the remote sensor platform also has a bearing on choice of film speed. To compensate for the degrading effects of image motion, one must use a fast shutter speed and therefore a fast film to reduce blurring. However, as noted above, fast films have lower resolutions.

In general, black-and-white films have higher resolution than color or color-infrared films of comparable camera speed.

The most common type of film used for aerial mapping and photointerpretation is panchromatic film (see figure 2-5). Since panchromatic film is sensitive to the same wavelengths as the human eye (about 0.36 to 0.72 micrometers), the relative tonal values of objects on panchromatic photographs are similar to those seen by the human eye--a characteristic which facilitates the photo-identification process. Although panchromatic film is excellent for distinguishing between objects of different colors, it lacks sensitivity in the green portion of the electromagnetic spectrum, thus making distinctions between vegetative cover types difficult. Panchromatic film is the least expensive of the aerial films to process and develop.

Color aerial films are basically of two types--reversal and negative films. Reversal films, after the first stage of developing, are positive transparencies. Negative films, however, yield a negative transparency. A black-and-white reproduction of a color photograph (see figure 2-6) can be used for comparison with a panchromatic print (see figure 2-5).

Today's color aerial films have improved speeds, definition, and less granularity. When used with appropriate filters to reduce haze effects, color aerial films increase the photointerpreter's ability to distinguish and identify forest types, degree of sediment load

Figure 2-5.--Black-and-white mapping photograph of downtown St. Louis. Notice the dark gray tones of the buildings and the light gray tones of nearby parking areas.

Figure 2-6.--Black-and-white reproduction of a color photograph of downtown St. Louis. Notice the lack of vegetation associated with the central business district (CBD).

in water bodies, and other landscape and manmade features exhibiting distinctive colors.

Aerial color-infrared (CIR) film, originally known as "camouflage detection film" and occasionally referred to as "false-color film," is sensitive to both the visible and reflected infrared portions of the electromagnetic spectrum (approximately 0.4 to 0.9 micrometers). Therefore, instead of being sensitive to blue, green, and red reflected light, its emulsion is sensitive to green, red, and infrared light when exposed through the required yellow (minus-blue) filter.

Aerial color-infrared film has excellent haze-penetrating capability because the yellow

filter eliminates the scattered blue wave lengths comprising most of the haze. In addition, since it is more sensitive to the near-IR portions of the spectrum, it is very useful in distinguishing land cover types based on different moisture contents. For this reason, it is used to discriminate camouflaged areas and diseased vegetation from healthy vegetation. Healthy vegetation appears red to magenta on CIR photographs whereas diseased vegetation appears darker red.

Color-infrared film is also helpful in identifying land/water interfaces, deciduous versus evergreen forest types, wetland areas (grayish-green to dark magenta colors), silt-

Figure 2-7.--Black-and-white reproduction of a color-infrared photograph of downtown St. Louis taken 3 months later. Note the loss of detail in shadow areas.

laden (light blue to white) versus clear water (dark blue to black) bodies, and delineating central business district (CBD) areas (bluish white) (Sabins, 1978, p. 44; Richason, 1978, p. 202-204). A black-and-white reproduction of a color-infrared photograph (see figure 2-7) may be compared for tonal differences with the panchromatic print (see figure 2-5) and the black-and-white reproduction of a color print (see figure 2-6).

Aerial Cameras

Aerial cameras can be classified by use (mapping, reconnaissance, or special), type (frame, panoramic, strip, or multiband), angular field of view (normal angle--up to 75°, wide angle--75° to 100°, super-wide angle--over 100°), and focal length (short--up to 6 inches, normal--6 to 12 inches, long--over 12 inches) (see Slama, 1980, p. 187-277). Probably, the most important distinction in cameras concerns their use--particularly mapping versus reconnaissance cameras.

Mapping cameras, often referred to as metric or cartographic cameras, are equipped with high-quality lenses to obtain the highest possible resolution and to reduce photographic distortions. Accordingly, the resulting photographs allow precise photogrammetric measurements. Aerial mapping cameras generally are of the frame type; that is, a camera in which an entire frame or format is exposed simultaneously through a lens that is a fixed distance from the film plane. Their total

field of view (angular coverage) across the diagonal is from 90° to 120°; that is 45° to 60° either side of the vertical position of the camera. Aerial mapping frame cameras generally use a 9- x 9- inch (23- x 23-cm) film format size.

The black-and-white photograph shown in figure 2-4 was taken with an aerial mapping frame camera. Section 6 of this guide, "Photointerpretation Keys for Missouri," contains various photographs taken with aerial frame mapping cameras.

Reconnaissance cameras are designed to provide maximum image resolution and only moderately good positional accuracy. These cameras are primarily used for intelligence gathering, land use change detection, and environmental monitoring. Reconnaissance cameras can be of the frame type or the panoramic type (see Reeves, 1975, p. 282-283). The large-scale photographs in the photointerpretation keys (Section 6) were acquired with cameras housed in an Enviro-pod. The Enviro-pod contains two KA-85A panoramic reconnaissance cameras. The cameras have a 3-inch focal length, 40° x 130° angular coverage (that is, 40° front-to-back along the flight line and 130° side-to-side perpendicular to the flight line), and a 70-mm-wide film. The cameras are mounted in a two-section aluminum housing. The camera in the forward section takes vertical photographs, while the camera in the rear section takes forward oblique photographs 45° down from the flight horizon. Figure 2-8 shows the Enviro-pod camera system strapped to a Cessna 172 aircraft.

Figure 2-8.--Cessna 172 aircraft with Enviro-pod camera system.

Although the cameras exposed color reversal film, the illustrations appearing in this guide are produced in black-and-white. Normally, exposures were made from an altitude of approximately 2,500 feet above mean ground level. Since the cameras have a 3-inch focal length, the scale at the center of each vertical photograph is approximately 1:10,000. Away from the center of the photograph, particularly near the sides, the scale becomes smaller and distortions increase significantly.

Since special-purpose cameras such as multiband cameras and special-effects cameras will not be discussed in this guide, the reader may wish to refer to Reeves, 1980, pages 187-232, for further information.

Although it is desirable to have mapping and/or reconnaissance aerial photographs, one should not overlook the utility of the hand-held camera. Photographs obtained from these cameras can be used to document land use changes and to verify photointerpretations. The traditional viewing angles offered by these cameras are more easily related to the understanding of land use and land cover categories. Therefore, the photointerpretation keys will often display ground-level or low-altitude snapshots of the objects being described to further assist the user in recognizing a particular land use or land cover type.

Photointerpretation

Photointerpretation is the detection, identification, description, and assessment of the significance of objects and patterns on a photograph. With respect to land use mapping, photointerpretation requires that land areas

be identified and assigned (classified) to a category in accordance with a land use classification scheme. In addition, the photointerpreter must follow specification guidelines for minimum area size and/or width measurements, density of occurrence (for example, four structures per 10 acres), and other relevant criteria to ensure consistent cartographic delineation of land use types.

The U.S. Geological Survey uses the classification scheme developed by Anderson and others (1976) and the mapping specifications (guidelines) as presented by Loelkes (1977).

Almost everyone can recognize and subsequently classify natural and manmade (cultural) features or objects from a vertical aerial photograph. Through our visual experiences, we unconsciously assemble a mental image library of recognition characteristics that describe the outward or physical appearance of an object--either natural or manmade. Typical characteristics are patterns, size, shapes, tones (gray-scale values on black-and-white photographs) or colors, textures (degree of roughness as exhibited on the photograph), shadows, and site associations.

Pattern. One of the most intriguing recognition characteristics of natural and manmade features are the patterns they make when viewed from the air. For example, an orchard planted in evenly spaced rows displays a characteristic grid pattern. The pattern of houses is significantly different for older, inner-city residential neighborhoods when compared to newer, suburban residential neighborhoods. Common terms used to describe landscape patterns include linear, circular, rectangular, square, concentric, radial, symmetrical, regular, irregular, random, and busy or congested.

Some features may be discernible as patterns at only certain scales. For example, an orchard becomes a texture at a smaller scale and a series of orchards may once again reveal a pattern at an even smaller scale.

Size. Both relative and absolute size aid in identifying features; for example, note the relative size differences between shrubs and trees and the absolute size difference between two parking lots. Because of the number of people who arrive each day, a shopping center requires more parking spaces than an industrial plant. Relative size comparisons are possible from an unscaled photograph; absolute size measurements require that the photographic scale be known or calculated.

Shape. Manmade objects tend toward straight linear shapes while natural features such as rivers or lakes tend toward irregular shapes with generally irregular boundaries. Easily recognized shapes include tennis courts, ball parks, shopping malls, highway cloverleaves, and schools. The terms used to describe shapes generally parallel the terms used to describe patterns.

Tone and Color. Photographic tone is the characteristic shade of gray exhibited by black-and-white photographs and is a function of light reflectance characteristics. Once a photointerpreter learns the different reflectance characteristics of objects, he or she can use this knowledge to help identify different land use types. For instance, cultivated fields tend to be darker than fallow fields, deciduous forests are lighter than evergreen forests, and commercial areas are lighter than residential areas. In general, higher moisture content yields darker tones.

Although the human eye can separate only 200 gray-scale values, it can separate over 5 million color combinations based on hues, values, and chromas (Reeves, 1975, p. 268). Because it is harder to learn to recognize objects by their tones (values) of gray than by color, it is easily understood why many interpreters prefer color photography. For example, Heller reported that the accuracies with which tree species could be identified were 17 percent higher on large-scale color transparencies than on panchromatic prints of the same scale (Lintz, 1976, p. 144).

Texture. Photographic texture is a function of the size of objects photographed and the scale of the photograph. Texture refers to the degree of roughness exhibited in a photograph.

On black-and-white aerial photographs, it is the arrangement of tonal repetition in objects which produces the texture characteristic. On large-scale photographs (for example, 1:4,800), individual tree crowns might be recognized, while on smaller-scale photographs (1:24,000 and smaller), the tree crowns are so small that only a texture appears. In general, coniferous forests exhibit a smoother texture than deciduous forests. Likewise, pasture provides a smoother texture than rangeland. Commonly used terms for texture are coarse, medium, smooth, fine, and mottled.

Shadow. Although most aerial photographs are obtained within 2 hours of solar noon, any shadows cast by objects can further aid in identification of an object. For example, the shadow cast by a cross helps to identify a

church, or the shadows cast by communication towers, monuments, trees, bridges, or oil tanks can also provide information to help verify their identity.

Shadows may also help to determine the size and height of an object. Knowing the scale and Sun angle of a photograph, one can measure the length of a shadow and calculate an object's height. If a shadow is cast by an object of known height (for example, a TV tower), a ratio calculation can approximate the unknown height of another object.

Site Association. Natural and manmade features often occur in certain places or in proximity to other objects. For example, willow trees are natural occurrences on floodplains or river sandbars. Likewise, cultural landscapes follow certain patterns of development. Elementary schools are located away from main traffic arteries, while shopping centers and other commercial establishments are found along or at the junction of major transportation routes. Heavy industry locates near railroads or along navigable waterways. High schools frequently have recreation areas and sports fields.

Interpretation Aids

The photointerpreter should not restrict identification of objects on photographs solely to the photographs. Any additional information should be used that will aid in the identification process. Reference materials, comparative photographic coverage, magnifiers, and stereoscopic viewing can each play a beneficial role in photointerpretation and verification.

Reference Materials. Perhaps one of the most useful sources of auxiliary reference information is the mental image library which a photointerpreter acquires by residing in a specific geographic area. However, the job of the photointerpreter normally extends well beyond his own geographic area. Lacking personal knowledge, one can refer to available planning and resource studies, maps, checklists, photointerpretation keys, or recognition manuals.

Planning and resource studies are usually available from local or regional agencies. Quite often, planning agencies have compiled various thematic maps, such as land use maps, which can also be of assistance to the photointerpreter.

Topographic maps, which present the horizontal and vertical positions of natural and manmade features, are readily available from the U.S. Geological Survey through its National

Cartographic Information Centers (NCIC) and through selected dealers in most larger cities. Topographic maps are very useful in identifying elevation interrelationships; for example, the occurrence of wetland tree species in low-lying, moist areas. Topographic maps further assist the photointerpreter by displaying detailed natural and manmade features from which additional significant information can be derived.

Checklists can give natural or manmade features which may occur in a geographic area or which are known to occur in proximity to one another. For example, Avery (1977, p. 24-25) has prepared a list of the kinds of features commonly occurring on aerial photographs. In addition, checklists are generally available for most natural resource professions (for example, see Avery, 1978, p. 13).

Photointerpretation keys illustrate recognition characteristics of particular features or groups of objects.

There are two types of photointerpretation keys: selective and elimination. Selective keys, of which this guide is an example, provide typical illustrations and descriptions of features in a specific category. The photointerpreter selects the key example that most nearly agrees with the object to be identified.

Elimination keys require the photointerpreter to follow a step-by-step elimination process from the general to the specific until the possible identification has been narrowed to one choice. This type of key is also called a dichotomous key (Avery, 1977, p. 25-26).

Finally, recognition manuals have been used primarily by the military to assist photointerpreters with recognition of military equipment: airplanes, ships, tanks, etc. More recently, recognition manuals have become available for natural resource features like tree species and for certain types of manmade features. For example, the State of Texas prepared a recognition manual for use in determining substandard housing structures (Texas Office of the Governor, 1972).

Stereoscopic Viewing. Stereoscopic viewing permits the photointerpreter to view objects in three dimensions and, because of the magnification of the viewing instrument, at a slightly larger size. With binocular vision, the photointerpreter views objects from slightly different angles with each eye, which

the brain interprets as relative distance. People having vision in only one eye are unable to view an object from two angles simultaneously, and therefore do not possess stereoscopic depth perception. Binocular vision can be simulated through use of aerial photographs taken of the same area from two different positions. The area common to both photographs can then be viewed in three dimensions.

The ability to view an object or feature stereoscopically adds yet another dimension to photointerpretation, particularly in identifying and differentiating vegetative types. Selected stereopairs have been included in the photointerpretation keys (section 6) where three-dimensional viewing would assist in identification.

Magnification. Quite often, even though a photograph's resolution has captured sufficient object detail, the photointerpreter is unable to recognize an object because of the photo's small scale. Magnifying equipment can enlarge the object and thereby add to the photointerpreter's ability to identify various features.

Comparative Coverage. Certain vegetative features (for example, deciduous trees) can be more easily identified if comparative photographic coverage exists. Since deciduous trees lose their leaves, comparative late fall or winter photographs facilitate the differentiation of deciduous from coniferous trees.

In addition to using seasonal photography, the photointerpreter may have access to color, color-infrared, or different-scale photographs. Therefore, the availability of comparable coverage should always be investigated.

Summary

Land use and land cover interpretation from remote sensing products requires knowledge of system components and characteristics of conventional aerial photographs--resolution, scale, platforms, and film and camera types. An understanding of how components interrelate to produce the final product is a key to successful photointerpretation.

Land use and land cover interpretation requires assignment of features to land use and land cover categories. The following section is devoted to this topic.

SECTION 3: LAND USE AND LAND COVER CLASSIFICATION SYSTEMS

Development of the Land Use and Land Cover Classification System

Background

Development of a regional comprehensive plan for natural resources is based, at least partially, on such factors as land use, soils, slope zones, geology, and drainage areas. Land use information, a main ingredient to the planning function, is an example of data generally not contained in a form suitable for correlation. Since land uses change faster than any other factor usually included in the planning process, land use information must be made available as quickly as possible.

Federal, State, and local agencies, as well as private consultants, have been producing land use and land cover maps for many years. These maps were compiled for specific programs or projects and have used a variety of land use and land cover classification schemes. These classification schemes were, for the most part, designed to meet the requirements of a particular program or project, and have such a diversity of content as to make them difficult to combine into a single comprehensive map.

U.S. Geological Survey Land Use And Land Cover Classification System

Knowledge of the character and utilization of land resources must be available if land resource-related problems are to be understood and controlled. In order to adequately inventory land resources, however, a classification system is needed to ensure that the data on cover characteristics and discernable activities related to land resources are objectively and consistently classified. Such a classification system has been developed by the U.S. Geological Survey for the national land use and land cover mapping program.

Land use surveys have been conducted for centuries, primarily for taxation. Agencies at all levels of government currently collect land use-related data for planning and analysis of land resource utilization. Such data are necessary if problems related to environmental degradation, loss of agricultural lands, wetlands, and wildlife habitats are to be reconciled with the need for sustained economic growth and energy development. Unfortunately, the result of many past inventory efforts has been duplication of effort and, conversely, data that subsequent to its first use, are of very limited value even when used for similar purposes.

The need for standardization among various agencies and recent developments in remote sensing and data processing technologies precipitated the U.S. Geological Survey's involvement in formulating a land use and land cover classification system. In 1971, an Inter-Agency Steering Committee on Land Use Information and Classification was formed including representatives from USGS in the Department of the Interior, the National Aeronautics and Space Administration (NASA), the Soil Conservation Service (SCS) of the Department of Agriculture, the Association of American Geographers, and the International Geographical Union.

The Committee sought to develop a classification system that would accommodate data from remote sensors on high-altitude aircraft as well as from conventional sources such as topographic maps or ground surveys. Although the Committee was formed to standardize classification used by Federal agencies, it was clear that a standard system could also provide a base for local, regional, State, and other agencies to use in formulating more detailed, compatible classification systems.

From the work of the Committee, as well as from consultation with States and other public agencies that had worked with classification systems employing remotely sensed data, the late James R. Anderson, USGS, developed a prototype for a national system. The system was designed with consideration of other classification systems and inventory efforts in use by the Federal government. This included the land use coding scheme promulgated by the Bureau of Public Roads in 1965, the Inventory of Major Land Uses conducted by the Economic Research Service of the Department of Agriculture, and the Conservation Needs Inventory of the SCS. The original version of the USGS classification system was published in Circular 671 in 1972.

Previously, the USGS had tested several classification systems in a series of pilot projects including the Census Cities Project, the Central Atlantic Regional Ecological Test Site (CARETS) study, the Phoenix Pilot Project, and the Land Use Mapping Project for the Ozarks Regional Commission. The latter project utilized high-altitude photographs and 1:250,000-scale topographic maps for the mapping effort. Many of the techniques involved in this project evolved into those used in the national land use and land cover mapping program now carried on by the USGS.

The categories of land use and land cover in Circular 671 were delineated to the second level of detail. Land use was defined as man's activities related to land resources, and land cover, as vegetation or artificial structures covering the landscape. The distinction is important, particularly for this classification system which, in contrast to other systems, attempted to cover all elements of the landscape in an equitable degree of detail.

Circular 671 suggested that Level I land use and land cover categories could be mapped using satellite imagery alone. Level II categories would require high-altitude aerial photographs (1:40,000 to 1:120,000) and the supplemental data which could be obtained from topographic maps. Level III categories would require medium-altitude photographs (1:20,000) combined with information from detailed topographic maps and other supplemental data sources. Level IV categories would require low-altitude large-scale photographs (larger than 1:20,000), but actually most data would be obtained from supplemental sources such as detailed large-scale maps or ground surveys.

The classification system proposed in Circular 671 was revised after several years of additional testing and research. The revised system is presented in USGS Professional Paper 964 (Anderson and others, 1976; see table 1-1 preceding). Like the prototype system, the revised classification system provides a Level II delineation of land use and land cover categories. General criteria for developing the classification system include the following considerations:

(1) The minimum level of interpretation accuracy in identifying land use and land cover categories from remote sensor data should be at least 85 percent.

(2) The accuracy of interpretation for the several categories should be about equal.

(3) Repeatable or repetitive results should be obtainable from one interpreter to another and from one time of sensing to another.

(4) The classification system should be applicable over extensive areas.

(5) The categorization should permit vegetation and other types of land cover to be used as surrogates for activity.

(6) The classification system should be suitable for use with remote sensor data obtained at different times of the year.

(7) Effective use of subcategories that can be obtained from ground surveys or from using larger scale or enhanced remote sensor data should be possible.

(8) Aggregation of categories must be possible.

(9) Comparison with future land use and land cover data should be possible.

(10) Multiple uses of land should be recognized when possible.

The categories of land use and land cover presented in Professional Paper 964 (Anderson and others, 1976) are being used for the national land use and land cover mapping program. Operational definitions of the classes and specifications for the national land use mapping effort are provided in USGS Open File Report 77-555 (Loelkes, 1977).

Characteristics of the USGS Classification System

The USGS classification system is compatible at the more generalized levels with previously developed classification systems and inventory efforts. An important difference between the USGS system and others is the fact that the system is designed to support extensive surveys of land use and land cover with consistent and uniform delineation of all elements of the landscape. This is in contrast to other systems in which one or a few land use and land cover types are differentiated in great detail while others are omitted or classified as miscellaneous.

An example of such a system is the Standard Land Use Coding (SLUC) system developed by the Bureau of Public Roads in conjunction with the Urban Renewal Administration (see table 3-1). This system based its classes upon economic activity and utilized, insofar as possible, the codes and description activities employed by the standard classification system of the U.S. Department of Commerce. The resultant system was extremely detailed so that groups of classes could be formed to meet the specific needs of different communities. Data for this system were generally collected through field survey methods or local knowledge of an area.

The SLUC system has been employed successfully in urban areas for community, transportation, and other forms of urban planning. Unfortunately, this classification system does not provide enough categorical detail for land areas which do not have an established economic activity related to the land resource. Such areas are simply aggregated into the category of "undeveloped land and water areas." For the purpose of land resource management and environmental impact assessments, this obviously does not provide enough detail. Wetland areas, wildlife habitat areas

*Not elsewhere coded.

associated with particular vegetative cover types, and other diverse types of land cover conditions are not differentiated in the SLUC system.

A second major distinguishing characteristic of the USGS system is that it is a hierarchical system. Numerical codes are used for the various categories in the USGS system and the number of digits reflects the level of detail in the classification system being used (table 1-1). The first digit identifies the Level I class, the second digit the Level II class, and so on.

With a hierarchical scheme, the derivation and definition of the categories are more easily understood. Also, the hierarchical nature of the USGS system helps promote development of more detailed classification systems. At Level III, for example, the Level II category "Cropland and Pasture" (21) can be divided into two additional categories--211 (Cropland) or 212 (Pasture).

The State of Florida developed such a system which it adopted for use by State and regional agencies (see table 3-2).

Table 3-2. State of Florida Level I, II, and III, land use codes

¹Only the Commercial and Services categories are presented here; however, a complete classification system was developed²U.S. Executive Office of the President, 1972³U.S. Urban Renewal Administration, 1965

The USGS also worked with the Water Pollution Control Department of Kansas City, Kansas, to develop a classification system for land use at Level IV (table 3-3). In addition, the system was cross-referenced to the Standard Land Use Coding Manual and the Standard Industrial Classification scheme.

It should be noted that a complete subdivision of all categories is not essential.

Table 3-4. Sample Level IV forest classification system

(Same categories would be repeated for Evergreen Forest Land and Mixed Forest Land; from Cook, 1980, exhibit 3, p. 1-2)

41	Deciduous Forest Land
411	10 - 39 Percent Canopy
4111	Sawtimber
4112	Poles
4113	Reproduction
4114	Mixed
412	40 - 69 Percent Canopy
4121	Sawtimber
4122	Poles
4123	Reproduction
4124	Mixed
413	70 - 100 Percent Canopy
4131	Sawtimber
4132	Poles
4133	Reproduction
4134	Mixed

Flexibility of the system allows modifications of the system to support a wide range of applications. For example, for forest management applications, it may be necessary to further subdivide the Level II categories of Deciduous (41), Evergreen (42), and Mixed Forest Land (43). These subcategories could be based on such factors as average stand height, crown closure density, or diameter of trees as indicated by their economic classes (see table 3-4).

For other applications, categories within the classification system can also be aggregated. In these cases, all lower level codes and categories can be grouped together to provide data for more-general codes and categories. As an example, acreage statistics for Level II categories 21, 22, 23, and 24 can be grouped together to provide statistics for Agricultural Land (Level I, code 2).

Summary

Inventories of land use and land cover require a standard classification system to ensure that data are objectively and consistently classified.

The USGS has fully defined a classification system to the second level of detail for the national land use and land cover mapping program. All elements of the landscape are provided consistent categorical detail. In addition, since the classification system is hierarchical in nature, it can be expanded to accommodate the need for greater detail.

With a viable land use and land cover classification system and suitable photographic source materials, one may proceed with the task of compiling a land use and land cover map.

SECTION 4: LAND USE AND LAND COVER MAPPING

Background

Land use and land cover mapping may be defined as "the systematic delineation of man's activities and the surface cover of the land." The maps produced by the USGS are specialized in that they use a unique set of mapping specifications and a classification system. They depict the land use and land cover classification categories and associated maps uniformly for the entire United States (see table 1-1).

The national land use data base was developed with three constraints in mind: (1) the mapped data should be compiled and published at the largest scale possible; (2) the map series utilized as a base must be complete for the entire United States; and (3) the map series used as a base must have a geographical format suitable for computer application.

The standard 1:250,000-scale topographic map series is the largest scale available that also meets the other requirements. Therefore, the 1:250,000-scale map series was selected as the standard base map for land use and land cover mapping. Certain areas, however, have been mapped at the 1:100,000-scale using the same specifications used as for the 1:250,000-scale map compilations.

For future efforts, it has been decided that revision of land use/land cover maps will be completed on the 1:100,000-scale map bases wherever possible. There have also been demonstration projects completed at a scale of 1:24,000. These large-scale land use and land cover mapping projects were limited in size and designed to test utilization of the land use and land cover classification system and specifications at larger scales.

When the land use and land cover program was initiated, the USGS determined which other types of map overlays should be correlated with the land use and land cover maps to provide the user community the greatest effectiveness in problem solving. From the multitude of maps considered, ranging in complexity from county boundaries to detailed soil types, the following map themes were selected: (1) political boundaries, (2) hydrologic units, (3) census county subdivision, (4) Federal land ownership, and (5) State land ownership.

The last two are only prepared when an entire State is compiled. Also, the State land ownership overlay is compiled only when a State furnishes the data.

The associated maps portray natural or administrative information and provide the user with the opportunity to utilize, either individually or collectively, the land use and land cover maps and data to produce graphic or statistical data for the areas portrayed on the associated maps. The mapping system is constructed in such a way that the graphical and statistical land use and land cover data can be related to other resource data sets such as soils, geologic, and hydrologic data as well as demographic and socioeconomic data.

Product Preparation

The Geological Survey's land use and land cover and associated maps are compiled in the Western Mapping Center, Menlo Park, Calif.; Rocky Mountain Mapping Center, Denver, Colo.; Mid-Continent Mapping Center, Rolla, Mo.; or Eastern Mapping Center, Reston, Va.

Before an area is authorized for compilation, it is necessary to determine the availability of source materials for the area. The prime source materials for small-scale land use mapping are aerial photographs which meet the following specific requirements: (a) the photographs should not be more than 3 years old; (b) there should be no more than 10 percent cloud or snow cover; (c) photographic scale should be 1:80,000 or smaller; (d) photographs must be tilt correctable when necessary; and (e) photographs should be acquired during leaf-off conditions.

Although all photographic source materials are examined for possible use, the most commonly used in the national land use mapping program are:

1. Color-infrared photographs taken at altitudes between 60,000 and 65,000 feet (scale between 1:120,000 and 1:130,000).

2. Black-and-white panchromatic photographs taken from altitudes of approximately 40,000 feet (scale of 1:78,000).

3. The National High-Altitude Photography (NHAP) program; scheduled to provide high-altitude photographic coverage for the entire United States every 7 years. The photographs collected consist of color-infrared photographs from a camera with an 8.25-inch focal length, and panchromatic high-resolution photographs taken with a 6-inch focal length camera.

For small areas not having photographs meeting the requirements, searches are made from other sources such as the Agricultural Stabilization and Conservation Service of the U.S. Department of Agriculture.

When mapping land use and land cover at intermediate scales of 1:24,000 to 1:100,000, the photographs should be less than 18 months old at completion of compilation and range in scale from 1:20,000 to 1:60,000, depending on the scale of compilation. The remaining photographic requirements are the same as those for the 1:250,000-scale mapping program.

The source materials needed to compile the associated maps are gathered from various State and Federal agencies. The information needed to compile the political units map and the census county subdivision maps are obtained from Geological Survey topographic maps and the Bureau of the Census. The Geological Survey, Water Resources Division, provides published Hydrologic Unit State Maps at a scale of 1:500,000 from which the hydrologic units maps are compiled. State land ownership maps are compiled under a cooperative agreement with a State only if the source material is furnished by the State in a format acceptable for compilation. The Federal Land Ownership maps are compiled from data obtained from the various Federal agencies whose data will be shown on the finished map.

Other types of maps can be added to this set, such as soils, geology, utilities, highways, and floodplains. When adding other mapped data sets to the original land use and land cover data sets, data should be compatible in scale and content.

Field Activities

Field activities support two distinct phases of compilation of land use and land cover maps. These are (1) precompilation fieldwork, and (2) field checking of compiled sheets.

To accomplish precompilation field activities, the area is reviewed to determine the types and extent of land use patterns to be mapped. Air traverses, flown in a light aircraft at low altitudes (500 to 1,500 ft.) provide the opportunity to obtain low-altitude oblique photographs of the land uses. Data from the photographs are then plotted on a 1:250,000-scale topographic map and used along with a written report to brief the compiler on the area by comparison of the large-scale photographs with the vertical mapping photographs.

Post-compilation field checks allow the interpreter to classify difficult-to-interpret areas and to check the general accuracy of the map. If classification of problem areas cannot be resolved from an aircraft at a low altitude, a ground visit to the site is made. The areas

covered by field check photographs are plotted and a field report is written. The necessary corrections are made, and the map is forwarded for final reproduction.

Land Use and Land Cover Minimum Size Specifications

The minimum size specifications for delineation of the 1:250,000- and 1:100,000-scale land use polygons are as follows.

Polygons to be delineated must meet minimum size requirement, regardless of whether they were published at 1:250,000 or 1:100,000. The following categories must have a minimum area of 4 hectares (10 acres): all Urban or Built-up Land (11-17); Confined Feeding Operations (23); Other Agricultural Land (24); Water (52-54); Strip Mines, Quarries, and Gravel Pits (75); and Transitional (76), if urban. All other categories of land use and land cover have a minimum area of 16 hectares (40 acres).

In all categories mapped using a 4-hectare (10-acre) minimum mapping unit, the minimum width of a feature must be 200 m (660 ft.). This minimum width precludes delineation of very narrow or very long 10-acre tracts. All categories mapped using the 40-acre minimum mapping size use 400 m (1,320-ft.) minimum widths. Exceptions to this specification are limited access highways and all "double-line" streams on the 1:250,000-scale base map. Such areas have to have a minimum width of 100 m (300 ft.).

Land Use and Land Cover Delineation

Interpretation of the detail on aerial photographs and transferral of this information to the map base is accomplished by stereocompilation techniques or direct detail transfer. When stereocompilation techniques are used, maps are compiled at 1:250,000 or 1:100,000 scale with the use of a pantograph attached to a photogrammetric instrument (see figure 4-1).

The direct detail transfer technique (also known as monoscopic compilation) uses a modified microfiche viewer with 20x magnification (see figure 4-2). Using this technique, the photograph is scaled to fit the base map. In the case where the scale of a block of photography does not differ in scale by more than 3 percent, it is simpler to enlarge the base map to the average scale of the photograph. Transfer of land use polygon data from the photograph to the base map can be completed by sliding the photograph under the base map and

Figure 4-1.--Photogrammetric land use and land cover compilation.

Figure 4-2.--Direct detail transfer land use compilation.

aligning the photographic detail with the map detail. The detail viewed on the screen of a microfiche viewer can then be transferred to the map transparency by coordinating the image with the same image on the photograph positioned under the base map.

Generally, compilation by photogrammetric methods can be completed more quickly than by direct detail transfer; however, more time and effort are required for editing. With editing, the overall time required to compile any given area is found to be approximately equal for monoscopic and stereocompilation methods.

Associated maps are compiled on scribe coats at publication scale.

Political units map boundaries follow those county boundaries shown on the base map but must be verified with the County Subdivisions-Townships and Places maps from the Bureau of the Census. Political units map polygons are identified by five-digit codes obtained from the Geographic Identification Code Scheme (U.S. Bureau of the Census, 1972b).

Hydrologic unit boundaries and identifying eight-digit codes follow those shown on the State Hydrologic Unit Maps prepared by the U.S. Geological Survey. A legend of polygon unit names and codes is also compiled at this time from the USGS lists of "Boundary Descriptions and Names of Regions, Subregions, Accounting Units, and Cataloging Units," Water Resources Division, USGS, 1982.

The Census County Subdivision Map portrays census county subdivisions for nonmetropolitan counties and census tracts for Standard Metropolitan Statistical Areas (SMSA) as defined in the 1970 or 1980 Census of Population. Maps compiled prior to the 1980 census use 1970 census data, those compiled after the 1980 census use 1980 data. The political units boundaries from the Political Units Maps form the framework for delineation of the census county subdivisions. The County Subdivisions-Townships and Places map, and the maps from the appropriate Census Tracts: SMSA publications of the Bureau of the Census are used to obtain boundaries for this map. A legend of census county subdivision names and codes is also compiled at this time from the Geographic Identification Code Scheme (U.S. Bureau of the Census, 1972b).

The Federal land ownership map is compiled showing only surface areas of federally owned land occurring in units of 40 acres or more. A two-digit code is used to identify parcels of federally owned land.

The State Land Ownership map is completed only for those States which have a cooperative agreement with the National Mapping Division. Under this type of agreement, the agency must furnish the necessary compilation source information for compiling such maps. The code referencing system is designed separately for each State.

During the compilation process, all maps are checked with adjacent maps to ensure continuity. Map editing consists of an overall review of the manuscript for cartographic errors, such as missing identification numbers, broken lines, improper fittings, and any other obvious cartographic errors. In addition, a comparative review is made with the source

materials to ensure that map compilation meets specified requirements for photographic interpretive accuracy and delineation of polygons.

Quality Control

Quality control consists of an in-depth review of the map manuscript to determine if category definitions and specifications for interpretation and compilation have been consistently followed. A complete cartographic review includes reviewing the accuracy of interpretation, proper placement of identification numbers, adherence to specified minimum sizes for the land use and land cover categories and use of specified line weights. Errors are noted for correction on a stable-base overlay or diazo copy of the manuscript.

Three types of accuracy checks are performed. The first accuracy check is for interpretation. Various field validation techniques and processes are used to establish the accuracy of land use and land cover interpretations. The second accuracy check concerns delineation of polygons compared to boundaries existing on the Earth's surface. Since delineations are taken from photographic source materials, the outline is as precise as the scale of the photograph will allow. The third accuracy check is for positional accuracy. The positional accuracy of the maps must be consistent with that of the published map used as the compilation base.

In addition to quality control of individual sheets which make up the land use and land cover and associated map set, there must be a composite quality control of all sheets in the set. Table 4-1 shows some of the types of correspondence which must be achieved.

Final Reproduction and Release

After a final review, reproductions are made and the maps are released to open file in the appropriate regional mapping center along with a copy of the planimetric base. Copies are also sent to the various State cooperators and USGS outlets as required.

Land Use and Land Cover Mapping Specifications at Scales of 1:100,000 and Larger

Regional and local natural-resource managers often require that their land use and land cover maps be more detailed and at a larger scale. For more detailed and larger

scale land use maps, the source photographs must be more recent and larger scale and the minimum polygon size and minimum polygon width must be smaller. Table 4-2 illustrates the relations among the levels of land use and land cover classifications, base map scales, photographic scales, minimum polygon sizes and widths, and sources required for delineation of land uses.

To further illustrate these relationships, several land use and land cover maps at various scales and classification levels follow.

Figure 4-3 illustrates the Level I land uses around Lebanon, Mo. Figure 4-4 shows the same geographic area at a Level II land use. Specifications used for both compilations were those detailed in Open-File Report 77-555 for 1:250,000-scale compilations.

The 1:24,000-scale map compilations are the same areas as those set off by the heavy black rectangles in figures 4-3 and 4-4. The classification system used for the compilation of figure 4-5 followed a multilevel classification system prepared for the Kansas City, Kan., land use test and demonstration project as shown in table 3-3 (Sosinski, 1980). Figure 4-6 followed a classification system used by San Mateo, Calif. The specifications used for compilation were as follows: (1) polygons to be delineated had to have a minimum size of 2.5 acres for Levels II and III, (2) all categories mapped with this mapping unit size had to have a minimum width of 125 ft.

Summary

Compilation procedures and techniques used by the U.S. Geological Survey for land use and land cover mapping at a scale of 1:250,000 or 1:100,000 can be used to compile any scale natural resource thematic map. Specifications to compile mapped data, the level of classifications, and the different types of social and natural resource data input requirements, all fall under these procedures and techniques. The items must, however, be compatible in scale, detail, and specifications. Time spent in project planning to ensure compatibility of the project data will assure successful completion of a mapping project. Table 4-2 showed the relationship of these various aspects of land use mapping. The information contained in this table was prepared primarily for land use and land cover mapping; however, it can be expanded or modified to include other types of natural resource data requirements as well.

SECTION 5: LAND USE AND THE ENVIRONMENT

As the Earth's population has increased and man has become technologically more advanced, his needs for natural resources and space have also increased. These needs, although economically and socially beneficial, have often had an adverse effect on the environment. The shift from an agrarian to an industrialized society has at times changed a pristine environment to an environment of polluted air, water, and soil. Some areas have been polluted to the extent that they are no longer useful.

All uses of land and types of cover either produce or are impacted by some form of pollution. This may range from air quality problems caused by the natural decomposition of organic matter in forested areas, to the illegal disposal of hazardous waste materials. Some forms of pollution have purely aesthetic impact, while others are lethal. Recent episodes, such as the Love Canal area near Buffalo, N. Y., have dramatically shown the far-reaching implications of the improper disposal of chemical wastes. One of the purposes of this guide is to provide the user with some insight to the use of remote sensing and land use and land cover maps and to aid in the understanding of environmental/land use relationships.

Since most types of pollution result from the activities of man, it is easily understood why many of these pollution types are a direct result of man's use of the land. Consequently, an existing land use map, compiled from recent aerial photographs, can be an invaluable tool in attempting to access real or potential environmental problems. The products available through the U.S. Geological Survey's national land use and land cover mapping program can greatly assist environmental specialists and natural-resource planners by narrowing their geographic search area to those land use categories most likely to create pollution problems.

Application of remote sensing for environmental monitoring is well established and documented. Many governmental agencies whose mission involves resource management and mapping have utilized aerial photographs since the mid-1930's. Because of the time-consuming nature of ground investigations, it became readily apparent that only aerial images could provide information in a timely, efficient, and cost-effective manner.

Of the many agencies employing remote sensing, the Environmental Protection Agency (EPA), realized in the late 1960's the benefits which could be derived from imaging sensors.

Since that time, a variety of remote sensor studies have been made of regulated pollution sources.

A very basic type of study, an inventory of pollution sources, can be easily carried out using aerial photographs. While the majority of stationary point sources require permits, there are many nonpoint sources which do not. A nonpoint source is an area type source; examples include junkyards, construction sites, landfills, feedlots, and freshly tilled agricultural fields. The major problem associated with nonpoint sources is degradation of water quality caused by surface runoff entering both ground and surface water supplies. Aerial photographs provide an ideal means of analyzing large geographic areas for this type of pollution source.

A new analytical technique developed by EPA for detection of failing septic tank fields uses large-scale color and color-infrared photographs. The technique, used successfully in various regions of the country, is based on the fact that a failing system increases the nutrient levels and available moisture to surface vegetation thereby causing vigorous growth which can be readily observed on color-infrared photographs. It is believed that this technique has saved hundreds of thousands of dollars over conventional field investigations. Data from these studies are used to determine the need for new or expanded waste water treatment facilities.

Aerial images have also been effective in monitoring oil and hazardous materials spills. In such episodes, the images are obtained, processed, and analyzed in the shortest possible time--usually less than 24 hours--to provide information directly to cleanup personnel. A recent development has been installation of a color television camera in the oblique position of the Enviro-pod camera system (see figure 2-8). The aircraft's ground track is recorded on videotape and played back at the spill command post shortly after the plane lands. The vertical Enviro-pod camera photographs are retained for documentation and more detailed analysis at a later time. The television system has also been used to monitor aerial spraying of pesticides. A direct air-to-ground transmission system is presently being developed.

Environmental surveys using aerial imagery have proven invaluable in intensive site analyses of known potential hazardous waste sites. In addition to recent imagery, historical photographic coverage can often be obtained and analyzed, thereby providing a comprehensive site picture. The types of information extracted include areal extent, types of wastes disposed, presence of liquid

storage areas, offsite contamination, vegetation damage or stress, surrounding land use, and onsite or offsite drainage.

Use of imaging systems for environmental monitoring is, as yet, still in its infancy. The vast majority of pertinent data are presently collected using conventional photographic imagery. The Environmental Protection Agency, along with other governmental agencies, is investigating a number of other remote sensing monitoring methods such as laser fluorosensing; light intensification, detection, and ranging systems (LIDAR); and multi-spectral imaging systems. However, for detection, location, and analysis of pollution sources, the use of conventional photographs has been the most consistent and reliable method.

The basic types of pollution attributable to the Level I land use and land cover categories are discussed in the following paragraphs to facilitate an understanding of the sources of these pollutants and their potential effect on the environment.

Urban Pollution Sources

The main types of pollution in the urban environment are water, air, and noise. The first, water pollution, is caused primarily by improperly treated sewage and waste-water discharges. In residential areas, failing septic tank systems or overloaded sewage disposal plants are sources of water pollution. In commercial areas the large expanse of concrete and asphalt used for street paving and parking areas provide an impervious surface which allows rainfall runoff to convey residual tar, automobile fluids, and litter into streams and rivers. The predominant waste-water problem associated with industrial areas is brought about by the outdoor storage of raw materials and finished products. In addition, improper disposal of waste products can become a major source of pollution. Land used for transportation and utilities contributes to urban pollution primarily from the use of fossil fuels. Both the burning of fossil fuels and the storage and transportation of these fuels are potential pollution sources. Burning coal has also been directly connected to "acid rain." Runoff from highways, railroads, and airports is also among the list of potential water-pollution sources.

The other types of pollution, air and noise pollution, are generally caused by such

activities as railroads and airports as well as vehicular operation, industrial plant operations (especially plants burning various types of fossil fuels), and heavy construction operations. Although man's activities in the urban environment do constitute a wide range of potential pollution sources, not all of the Urban or Built-up Land uses are sources of pollution. Public parks, golf courses, lakes, and various other types of greenbelt areas are generally not urban pollution sources.

Agricultural Pollution Sources

The primary source of pollution from agricultural areas are nonpoint, or areal, in nature. Since agricultural practices require large field patterns to be economically efficient, it is of little surprise that these areas are, or at least may become, sources of nonpoint pollution.

Nonpoint pollutants are most often associated with chemical or physical water quality degradation. Following periods of moderate to heavy precipitation, overland runoff passes through agricultural areas, and chemical (such as pesticides and fertilizers) and physical (primarily surface soil particles) contaminants are carried to nearby water bodies.

Accordingly, farmers should be encouraged to use agricultural practices which will lessen the magnitude of nonpoint pollution.

Rangeland Pollution Sources

Rangelands are natural areas by definition and generally are not pollution sources.

Forest Pollution Sources

Forested areas, like agricultural areas, are prime candidates for nonpoint pollution contaminants. These contaminants, primarily loose soil particles and residual herbicides, insecticides, and fertilizers, like nonpoint pollution contaminants from agricultural areas, are transported to nearby water bodies by overland runoff.

Of the above contaminants, soil erosion is by far the greatest nonpoint pollution source resulting from silvicultural practices. Clear cutting activities and use of heavy machinery to construct logging roads are the main offenders.

Water Pollution Sources

Water bodies generally are not pollution sources. However, they serve as the transfer mechanism for chemicals, soil particles, and other organic pollutants that can impact the Earth's ecosystems.

Wetland Pollution Sources

Wetland areas can be subjected to a number of adverse environmental hazards created by human activities. Drainage systems act as transportation routes for distributing pollutants; dumping and filling activities may introduce toxic substances into nearby wetland areas; and adjacent agricultural activities may introduce fertilizers, pesticides, and animal wastes into nearby wetland areas.

Barren Land Pollution Sources

The only Barren Land categories that occur in Missouri are Sandy Areas other than Beaches; Strip Mines, Quarries, and Gravel Pits; and Transitional Areas. Of these categories, the Strip Mines, Quarries, and Gravel Pits category is the most frequent source of pollution. In addition to contributing to air and noise pollution, these areas are often a source of chemical and/or physical contaminants which can enter nearby water bodies.

The above pollution source descriptions are only generalizations. However, as each Level II land use and land cover category is covered in section 6 of this guide, more detailed environmental considerations will be included for that category.

SECTION 6: PHOTOINTERPRETATION KEYS FOR MISSOURI

INTRODUCTION

This section presents the land use and land cover photointerpretation keys and the possible environmental impact of each type of land use or land cover in Missouri. The interpretation keys follow the land use and land cover categories as shown in table 1-1. Each of the Level I land use and land cover categories has a brief general discussion followed by the Level II categories. Each Level II land use and land cover category includes a general description and the possible environmental impact of the category, and is illustrated by a number of sites. Each site is identified by (1) a site number, the general location of which is shown on a map of Missouri (figure 1-1), (2) a short title for the site, (3) the name of the nearest populated place, county, and State name, and (4) the location of each site by latitude and longitude.

In addition to the photographic illustrations, a more complete discussion of the category, and, where appropriate, an environmental statement are included with each of the sites.

In those cases where a second level land use and land cover category can best be represented by the most predominant type, only one site example is presented. In some cases, several examples are provided because of the need for more complete recognition and description of the category. For example, land use categories such as category 41 (Deciduous Forest) may be illustrated well with only one or two examples. However, category 11 (Residential) involves single-family homes, duplexes, garden apartments, trailer parks, high-rise apartments, and inner-city housing. The predominant example of this category, however, is the suburban single-family home. The prime illustration for this category is an area of single-family homes. However, because the category includes the other residential types, they are also illustrated with a very brief description.

Appendix A lists all site information by site number.

LEVEL I, CATEGORY 1 - URBAN OR BUILT-UP LAND

The areas which comprise Urban or Built-up Land are those of intensive use. These areas have a predominance of the land covered with structures. These structures are

associated with cities and towns, and other developments such as industrial and commercial areas. It is not necessary that the structures which comprise this category be within, or adjacent to, towns and villages; in fact, they may be completely isolated from urban areas.

As development progresses, land having less intensive or nonconforming use may be located in the midst of Urban or Built-up areas and generally will be included in this category. Agricultural land, forest, wetland, or water areas on the fringe of Urban or Built-up areas will not be included except where they are surrounded and dominated by urban development. The Urban or Built-up category takes precedence over others when the criteria for more than one category are met. For example, residential areas that have sufficient tree cover to meet Forest Land criteria will be placed in the Residential category.

Category 11--Residential

Category Description. Residential land uses range from high-density multiple-unit structures to low-density single-family houses on large suburban lots. Included in this category are single-family residences, apartments, condominiums, mobile homes, recreational homes, and any other building or structure used as a residence. The most common residential type of this category is the single-family home.

Environmental Considerations. The residential category has potential for impacting the environment in several ways. Among these are sewage, waste-water, air, and noise pollution.

Sewage and waste water are a major source of water pollution directly linked to residential development. Direct sewage outfalls and the introduction of untreated sewage effluent into surface and ground-water sources are major pollution problems. Residential areas that are not served by collector sewers must rely on subsurface, on-site, sewage disposal systems (septic tanks) which may malfunction due to soil and geologic problems or adverse seasonal conditions. When septic systems fail towards the ground surface, the runoff of untreated or partially treated sewage effluent can be a major source of surface-water contamination and lake eutrophication, as well as being an immediate health problem to the community. When septic systems are used in areas where the soil is sandy and/or very permeable, ground-water contamination may

occur as the septic effluent moves too rapidly through the soil resulting in inadequate attenuation and filtration of biodegradable particles prior to reaching ground-water level.

Even in residential areas where collector sewer service is available, the waste-water treatment facilities may be inadequate or overloaded and cause the discharge of an effluent that does not meet water quality standards.

Other water pollution sources associated with residential areas include runoff from driveways, parking lots, and solid waste disposal areas (landfills). Surface waters may also be contaminated from runoff containing fertilizers and pesticides used in lawn and garden care.

Additional pollution sources associated with residential areas include air pollution from auto emissions, home heating furnaces, and fluorocarbons in aerosol sprays. Changes in microclimates can occur as a result of thermal discharges. Noise pollution can result from construction activity and nearby highways.

Interpretation Keys. Six residential sites are illustrated ranging from high-rise apartments in an urban renewal area to recreational houses on a lake in rural Missouri. The principal example of this category is a recent suburban residential development of single-family homes on the periphery of a large metropolitan area.

Site No. 1 (Single-Family Homes)
Location: Manchester
St. Louis County, Missouri
Geographic Coordinates: 38°36'N
90°31'W

The small-scale vertical mapping photograph, figure 6-1, shows an expanded view of this area of single-family residential homes. Most single-family residences exhibit the same photographic signature of pattern, tone, size, and symmetry. In the upper left portion of the photograph is a subdivision under construction (point A, figure 6-1). Notice how the ground is cleared of vegetation before construction is started.

In the design of subdivisions, there are always areas which cannot be developed because of the topography or hydrologic conditions. These areas are generally left as undisturbed areas of natural vegetation. Two such dark-toned areas, without streets and houses, are shown at A and B in figure 6-2.

Figure 6-1.--Small-scale mapping photograph of suburban residential area in Manchester, Mo.

Figure 6-2.--Low-level oblique photograph of wooded areas left undeveloped.

Streets with circular drives and cul-de-sacs are easily identified by their pattern and light tones.

Ranch-style homes with attached garages of various sizes and shapes can be seen equidistant and symmetrical to the streets (figure 6-3). Upon close examination, sidewalks and driveways are visible. Many of the driveways are probably made of a blacktop material as they are darker in tone than the streets.

In the center foreground of the large-scale vertical photo (figure 6-3, point A) a small park can be identified with its small pool, tennis courts, parking area, and lake.

Figure 6-3.--Large-scale vertical photograph of a subdivision layout and park.

Site No. 2 (Inner-City Residential)
 Location: St. Louis
 St. Louis County, Missouri
 Geographic Coordinates: 38°36'N
 90°14'W

Figure 6-5.--Large-scale photograph of inner-city residential area, St. Louis.

In most inner-city residential areas, particularly in the older sections of cities, residences are either duplexes or multi-family structures. A typical duplex is shown in figure 6-6.

The key identification features of inner-city multiple-family residences are the rectangular street patterns, closely spaced buildings with little or no yard space, garages behind the buildings accessible only by the alleys in each block, and the similarity of the shape of the buildings (see figures 6-4 and 6-5).

Figure 6-4.--Small-scale photograph of inner-city residential area, St. Louis, Mo.

Figure 6-6.--Ground photograph of multi-family inner-city residential area in St. Louis, Mo.

Many of the older sections of town have local commercial shops and schools intermixed with the residential areas. In figure 6-7, a commercial area is shown at A while a school is located at B.

Figure 6-7.--Low-altitude oblique photograph of inner-city residential area with commercial and school areas.

Site No. 3 (High-Rise Residential)
 Location: St. Louis
 St. Louis City, Missouri
 Geographic Coordinates: $38^{\circ}31'N$
 $90^{\circ}13'W$

High-rise residential areas may be either apartments or condominiums. These structures are generally 4 to 12 stories in height and may be found within the city limits or in the adjacent suburbs. The buildings, if more than one, are constructed in a geometric pattern (see figure 6-8).

Figure 6-8.--High-rise apartments in an urban renewal area. The stereogram gives an excellent view of the height of the buildings and their similar shapes and sizes.

For convenience of the residents, the parking facilities are located next to the building and around the periphery of the building area (figure 6-9).

Figure 6-9.--High-rise residential apartments with internal and external parking facilities.

These high-rise residences are located in an area of urban renewal. The area has undergone change since the photograph in figure 6-8 was taken in July 1974. The change is illustrated by the absence of buildings at A in figure 6-10, taken June 1980.

Figure 6-10.--Urban renewal area undergoing change.

The play area for the building tenants is shown in figure 6-11. This figure also illustrates the size of the buildings and the

walkways which connect each of the floors in adjacent sections of the complex.

Figure 6-11.--Ground photograph of high-rise recreational area, St. Louis, Mo.

Site No. 51 (Garden Apartments)
Location: Springfield
Greene County, Missouri
Geographic Coordinates: 37°11'N
93°19'W

Garden apartments are generally found in the suburban area on the outer fringes of larger cities (figure 6-12).

The structures are generally one to three stories in height. They are generally constructed in a rectangular pattern but can be almost of any design, from circular to star shaped. They are referred to as garden apartments because of large grass areas surrounding the buildings and separate entrances (figure 6-13).

Figure 6-13 illustrates garden apartments at A and common-entrance apartments at B. Notice the proximity of parking to the garden apartments as compared to the common parking areas provided for the apartments at the right.

In figure 6-14, which shows garden apartments in midst of single-family homes in Springfield, Missouri, the dark-toned apartments can be identified by their size, shape, and similarity. Parking areas in front of each building make the streets look wider. On the right side of the photo, four separate parking lots are visible at B. Garden apartments usually include recreational facilities within the building complex area.

Figure 6-15 is a ground photograph of typical garden apartments.

Figure 6-12.--Small-scale photograph of garden apartments, Springfield, Mo.

Figure 6-13.--Large-scale photograph of garden apartments in Springfield, Mo.

Figure 6-14.--Low-level oblique photograph of garden apartments in Springfield, Mo.

Figure 6-15.--Garden apartments in Springfield, Mo.

Site No. 52 (Mobile Homes)
 Location: Springfield
 Green County, Missouri
 Geographic Coordinates: 37°11'N
 93°22'W

Mobile homes can be found throughout the countryside, however, they are primarily located in suburban areas in courts or parks (figure 6-16).

Figure 6-16.--Mapping photograph of mobile home park at Springfield, Mo.

Most mobile homes are secured on a permanent foundation and usually parked in a trailer court or park. Large mobile homes are parked perpendicular to or at an angle to the

streets in the court. This practice facilitates the maximum utilization of a limited area. Mobile homes are long and narrow as compared to a house, lighter in tone, and are usually arranged in a regular pattern (figure 6-17).

Figure 6-17.--Large-scale vertical photograph of mobile home park, Springfield, Mo.

Utilities are generally run between the backs of the mobile homes, with a gas or oil tank and an electric meter for each home. The water and sewage lines also run between the homes. The general method used for sewage disposal outside the city limits is usually a sewage lagoon (A, figure 6-18). Figure 6-19 presents a ground perspective of a typical mobile home park.

Figure 6-18.--Mobile home park and sewage lagoon near Springfield, Mo.

Figure 6-19.--Ground photograph of a typical street in a mobile home park.

Site No. 89 (Recreational Homes)
 Location: Trenton
 Grundy County, Missouri
 Geographic Coordinates: 40°06'N
 93°44'W

Recreational homes are frequently very close to water bodies, or in wooded areas, and provide outdoor recreational activities easily accessible to their occupants. This recreation area borders Lake of the Woods. The key identification features of recreational home areas are the road patterns and the different sizes and shapes of the buildings, boathouses, and docks. The general scattering of houses and vacant lots are also common. Figure 6-20 illustrates a rectangular road pattern which gives way to separate access roads to each residence as one approaches the lakeshore.

Figure 6-20.--Small-scale mapping photograph of recreational homes at Lake of the Woods, Mo.

The various shapes and sizes of the buildings are indicative of recreational homes. These homes can be year-round residences or seasonal cabins. Boathouses and boat docks are visible at every lakeshore lot. Wooded areas are considered an asset in recreational developments and therefore are usually not removed during construction (see figure 6-21).

Figure 6-21.--Large-scale vertical photograph of Lake of the Woods residential area.

Figure 6-22 illustrates a recreational home site area with the scattering, almost random, placement of structures.

This particular site is associated with a rather large lake. There are large numbers of recreational areas developed in mountain-type terrain. The lot layout and building type are mainly the same as for lake development. The recreational facilities, however, are in the form of smaller lakes and golf courses which tend to be more centrally located within the development.

These examples illustrate a cross section of the various types of dwelling units which comprise the residential category. There are many other types which are variations of the examples shown, but these examples can be considered typical.

Figure 6-22.--Low-altitude oblique photograph of recreational home area.

Category 12--Commercial and Services

Category Description. Areas which contain structures predominantly used for the sale of products or services are classified as commercial. Included in this category are central business districts, shopping centers, commercial strip developments along highways, and junkyards. The main buildings, secondary structures, and supporting areas--office buildings, parking lots, landscaped areas, and waste-disposal areas--are also included in this category. Institutional land use, such as educational, religious, health, correctional, and military facilities are likewise included in this category. Cultural and recreational areas that can be identified on aerial photos, and included in this category, are commercial sports arenas, drive-in theatres, amusement parks, and commercial campgrounds. At military bases and institutional facilities, areas not specifically related to the purpose of the institution should be placed in the appropriate category.

Environmental Considerations. Commercial and Services land use areas share the following general potential for environmental effects. Extensive concrete and asphalt coverings cause

high rates of surface water runoff which can affect water quality and quantity. The runoff is capable of carrying residual tar, oil, automobile fluids, litter, and other solids into storm sewers and eventually into nearby streams. The extent to which water quality is affected depends upon where the water has traveled during its course. Quantity is influenced by the impervious layers blocking the percolation and absorption of water into the Earth to replenish the ground water aquifer supplies. Excessive runoff can cause flooding during heavy rainfalls in commercial areas or in nearby residential communities. Commercial areas in general have high rates of consumption and discharge of water. This results in large sewage volumes and depletion of local water reserves. Specific pollution hazards to water quality from commercial land uses include chemical contamination, thermal contamination, and over nutrification. Of all the commercial establishments in land use category 12, the activity which has one of the largest potentials for pollution is salvage yards. Salvaging of batteries and autos can contaminate soil, water, and air with toxic chemicals, lead, and iron oxides. The burning of auto interiors pollutes the air and can spread noxious odors to nearby communities.

Air quality is also affected by activities of commercial districts. High-volume traffic contributes exhaust emissions, dust levels are higher, and power generators can contribute particulate matter into the air. Airborne lint and debris can also effect air quality in these regions.

A noticeable byproduct from high-density commercial areas is excessive noise. Vehicles, heavy machinery, loudspeakers, and loading areas all contribute to abnormally high noise levels. These noises can be intensified by nonabsorbing building materials which can create echos. Noise levels may also be high at certain times in the neighborhood of concert halls, sports arenas, and fairgrounds.

The most noticeable detrimental environmental effect of a commercial area is its high-density land use. Sparse vegetation is common and "heat islands" are likely in sections devoid of greenery. The alteration of the terrain by heavy urbanization affects hydrology, vegetation, climate, and habitat.

Not all commercial land uses should be considered detrimental. Hospitals, schools, and other institutions provide open areas which, for the most part, are nonpolluting and aesthetically pleasing.

Interpretation Keys. Presented on the following pages are examples of Commercial and Services land uses in Missouri.

Site No. 4 (Shopping Center)
Location: Mehlville
St. Louis County, Missouri
Geographic Coordinates: 38°31'N
90°20'W

Large shopping centers are usually located in the suburbs of urban areas. The key identification features are large or interconnected buildings surrounded by well-paved parking lots and its location near an interchange or a four-lane divided highway for easy access and exit.

The small-scale mapping photograph (figure 6-23) shows the location of a Mehlville shopping center. The intersection of two interstate highways and major arterial streets provide easy and convenient access to the facility. Some of the surrounding residential and commercial development served by this shopping center is also visible. Since the date of the mapping photograph, July 1, 1974, the shopping center has expanded as evidenced in the photograph in figure 6-24, taken in June 1980. The dark rough-textured area to the west of this complex at A, is an area of trees which may eventually be converted to additional parking or other commercial activities. The photograph shows the large retail building completely surrounded by well-marked paved parking facilities.

Figure 6-23.--Small-scale mapping photograph of shopping center near St. Louis, Mo.

Figure 6-25 provides a ground perspective of the complex and some of the well-marked paved parking facilities.

Large shopping centers such as this site are built to have large covered malls. The various stores within the building open onto the outside of the building as well as the malls. When major chain stores are involved

with the shopping center, they will generally build with a characteristic design which will be evident in all shopping centers the store occupies.

Figure 6-24.--Large-scale vertical photograph of shopping center at Mehlville, Mo.

Figure 6-25.--Ground photograph of shopping center.

Site No. 53 (Shopping Mall)
 Location: Springfield
 Greene County, Missouri.
 Geographic Coordinates: 37°10'N
 93°16'W

The small-scale photograph shown in figure 6-26 locates a Springfield shopping mall in relation to major traffic arteries, surrounding residential structures, and other commercial land uses.

Figure 6-26.--Small-scale mapping photograph of shopping mall at Springfield, Mo.

The mall, Battlefield Mall, is more clearly shown in figure 6-27. In this large-scale photograph the building and parking lot can be easily identified by their lighter tones. The major traffic arteries provide easy access to the mall. Unlike shopping centers, malls have all of the stores under one roof with a walkway (mall) serving all stores.

Figure 6-27.--Low-level oblique photograph of Battlefield Mall, Springfield, Mo.

Figure 6-28.--Battlefield Mall's main entrance and parking lot.

Figure 6-28 shows the main entrance to the mall and associated parking facilities.

Site No. 79 (Central Business District)
 Location: Kansas City
 Jackson County, Missouri
 Geographic Coordinates: 39°06'N
 94°35'W

The stereogram presented in figure 6-29 provides an excellent perspective of the height of the buildings and the extent of parking within this central business district (CBD). Metropolitan CBD's have a large number of high-rise buildings. They usually are easily accessed by interstate bypass routes.

Figure 6-30 illustrates the built-up nature of CBD's. The CBD is the heart of the office/commercial activity of the city. The photograph clearly shows the high-rise buildings surrounded by large, lighter tone parking lots. Most of the lots are full; therefore, it's evident that these photographs were taken during business hours.

Figure 6-29.--Stereogram of portion of the Kansas City, Mo., central business district.

Figure 6-30.--Forward oblique photograph of Kansas City CBD.

Figure 6-31 presents a more familiar view of the Kansas City CBD.

Figure 6-31.--Ground-level view of central business district, Kansas City, Mo.

Site No. 49 (Medium-Size City CBD)
 Location: Lebanon
 Laclede County, Missouri.
 Geographic Coordinates: 37°41'N
 92°40'W

Figure 6-32 shows the central business district's growth away from the city's main

traffic intersection. The central business district originally developed along the railroad and is now expanding in all directions.

Figure 6-32.--Medium-size city central business district, Lebanon, Mo.

Figure 6-33, a large-scale vertical photograph, more clearly illustrates some of the recognition features of a medium-size town CBD. Notice the angle parking at A and the dark roofs of the three and four-story buildings at B.

Figure 6-33.--Large-scale vertical photograph of CBD, Lebanon, Mo.

Site No. 40 (Small-Town CBD)
 Location: Ironton
 Iron County, Missouri
 Geographic Coordinates: 37°36'N
 90°38'W

The main section of the central business district of Ironton is shown in figure 6-34. Small-town CBD's usually parallel the main traffic artery. Two- or three-story buildings line the street. Also shown in figure 6-34, in the west-central sector of the circle is the Iron County Court House. Notice the proximity of the residential structures to the CBD area. This is common in small-town CBD's.

Figure 6-35 provides a more traditional view of this small-town CBD.

Figure 6-34.--Large-scale oblique photograph of Ironton, Mo.

Fig. 6-35.--Ground view of CBD area, Ironton, Mo.

Site No. 46 (Commercial Strip Development)
 Location: St. Robert
 Pulaski County, Missouri
 Geographic Coordinates: 37°49'N
 92°10'W

Commercial development along major traffic arteries and access routes is often referred to as "commercial strip development." These areas provide retail goods and services to nearby residents. Figure 6-36 identifies two commercial strip development areas at A and B which serve the residents of St. Robert and military personnel from Fort Leonard Wood. Area A provides motel accommodations, fast food services, a general merchandise store, a car dealer, and other similar goods and services. Area B, particularly near the bottom of the photograph, provides services normally found to exist near military bases--bars, dry cleaners, groceries, general merchandise stores, a bank, and a TV repair shop.

Figure 6-36.--Mapping photograph of commercial strip development, St. Robert, Mo.

Figure 6-37 is a forward oblique photograph of the commercial strip development near the Fort Leonard Wood main gate. Notice the small parking lot facilities associated with the establishments at A, B, and C. In contrast, look at the large shopping center parking lot for the grocery/general merchandise complex at D. This particular example of commercial strip development illustrates how these types of retail goods and services can be provided without adversely affecting the traffic flow of a major traffic artery. Most larger urban examples of commercial strip development are characterized by commercial structures and parking lots abutting the street.

Figure 6-37.--Low-level oblique photograph of commercial strip development near main entrance of the army base at Fort Leonard Wood, Mo.

Site No. 54 (Motels)
 Location: Springfield
 Greene County, Missouri
 Geographic Coordinates: 37°15'N
 93°16'W

Figure 6-38 identifies an area of motels paralleling one of Springfield's major arterial streets (Glenstone Avenue). To the north of the area lies Interstate Highway 44. Motels are frequently located along major traffic arteries in proximity to interstate highways.

The key to identifying motels on small-scale photographs such as figure 6-38, in addition to their proximity to major transportation routes, is their linear structure, swimming pools, and individual parking facilities adjacent to the structures.

The large-scale photograph in figure 6-39 identifies swimming pools at A and two areas with swimming pools and tennis courts at B. Individual motel parking facilities are noted at C. Also identified in figure 6-39 is the North Park Mall at D.

Figure 6-38.--Mapping photograph of motels along Glenstone Avenue in Springfield.

Figure 6-39.--Forward oblique photograph of Springfield motels.

A ground-level photograph of one of the motels is shown in figure 6-40. Note the restaurant facilities nearby.

Figure 6-40.--Motel and restaurant on Glenstone Avenue in Springfield, Mo.

Site No. 55 (Suburban Office Building)
 Location: Springfield
 Greene County, Missouri
 Geographic Coordinates: 37°11'N
 93°16'W

Suburban office buildings range from two- to three-story structures to high-rise structures. Firms seeking facilities away from the central business district usually select less-expensive suburban locations with easier traffic access. Site 55 is a suburban office building (figure 6-42) in southeast Springfield which was recently constructed in place of a drive-in theater (figure 6-41). If one were categorizing land use as of the date of the mapping photography (January 1975), the drive-in movie theater would also fall under land use category 12.

Figure 6-42.--Office building with parking lots.

Figure 6-43.--Ground photograph of office building.

Figure 6-41.--Mapping photograph of drive-in theater, January 1975.

Modern office buildings may take on a variety of shapes and designs. Figure 6-42 presents a modern office building nearing final construction phases. The photograph was taken on a weekday in July 1980. Since there are no cars in the parking lot at A, one can assume that the office building was not yet ready for occupancy. Also visible, at B, were several construction trailers. The alternating rows of white and black of the building structure infer that the structure is multi-story. This fact is supported by the ground-level photograph shown in figure 6-43 taken in January 1981. Notice the cars parked in front of the building. Also notice in figure 6-42 at C the well kept grounds at the front of the building, the circular drive, and the area for temporary parking.

Site No. 69 (State Capitol Building)
 Location: Jefferson City
 Cole County, Missouri
 Geographic Coordinates: 34°50'N
 92°10'W

All Federal, State, and local government buildings and adjacent facilities and grounds are placed in land use category 12. Circled in figure 6-44 is the Missouri State Capitol Building and other nearby State office buildings and grounds. Situated adjacent to the Missouri River in Jefferson City, the Capitol and surrounding facilities and grounds are well maintained.

Figure 6-44.--State Capitol Building,
Jefferson City, Mo.

As with many State capitol structures, the Missouri State Capitol Building structurally resembles the Nation's Capitol Building. Figure 6-45 more clearly presents the building with its graciously adorned cupola, elevated main entrance and steps, and legislative wings for the Senate and House. Also common among State capitol buildings and grounds is the circular traffic pattern surrounding the structure.

Since parking is always a problem around State capitols, many States construct parking garages nearby. Figure 6-45 shows a multi-level parking garage at A. Also shown in this large-scale photograph at B is just one of many of the State's office buildings.

Figure 6-45.--Large-scale oblique photograph
of Missouri State Capitol.

Site No. 76 (Warehouses)

Location: Kansas City

Jackson County, Missouri

Geographic Coordinates: 39°06'N

94°32'W

Warehouses are normally large flat-roof buildings located near rail and/or highway transportation facilities. Although seldom located adjacent to major traffic arteries, they usually are located on secondary arterial streets to facilitate access by large semi-trailers. Figure 6-46 is a forward oblique photograph of a major general merchandise warehouse in east Kansas City. Notice the highway at A, the rail facilities at B, and the new warehouse structure at C. Unlike shopping centers which are seldom over two stories, large warehouses such as this one often have more than two stories. Also notice in this photograph the ease of access provided by the surrounding local streets (D).

Figure 6-46.--Low-level oblique photograph of
warehouse facility in east Kansas City.

Another recognition factor which can be employed in the identification of warehouses is the amount and location of parking facilities. Unlike shopping centers which have large, well-marked parking facilities adjacent to the retail structure, warehouses have much smaller parking lots located away from the structure (see figure 6-47, point A). Since most of the goods stored in the warehouse are moved by mechanized equipment, few employees are needed to operate a warehouse.

Figure 6-47.--Large-scale photograph of warehouse facility and employee parking area.

Figure 6-47 also shows the areas used to load and unload semitrailers (B). Additional semitrailers not in use are parked at C. A shopping center at D is just east of the warehouse.

A number of semitrailer units are parked at the warehouse loading dock in figure 6-48.

Figure 6-48.--Tractor semitrailers parked at loading dock.

Site No. 77 (Warehouse)
 Location: Kansas City
 Jackson County, Missouri
 Geographic Coordinates: 39°07'N
 94°34'W

Shown in figure 6-49 are just a few of some of the larger regional distribution warehouses located to the northeast of the Kansas City central business district. Notice the railroad facilities at A and the Missouri River at B.

Figure 6-49.--Mapping photograph of warehouse area in Kansas City.

As with the photorecognition characteristics noted earlier for site 76, figure 6-50 shows two other warehouses in which tractor semitrailer units play a major role. The warehouse at A is primarily served by tractor semitrailers, while that at B receives, and possibly ships, goods by rail as well as tractor semitrailers. Notice the six railroad boxcars at the loading docks on the east side of warehouse B. Also note the semitrailers parked on the north side of warehouse A and on the west side of warehouse B.

Figure 6-50.--Large-scale photograph of warehouse.

Site No. 72 (Auto Salvage Yard)
 Location: Columbia
 Boone County, Missouri
 Geographic Coordinates: 39°58'N,
 92°26'W

Auto salvage yards, such as the one shown in figure 6-51, are included in land use category 12. This particular auto salvage yard is well organized with autos lining both sides of dirt access roads. If not careful, particularly on small-scale mapping photography, a photointerpreter may at first glance believe the area is one of residential development because of the road patterns. However, on closer inspection, one realizes that the roads are too narrow and the rectangular objects (cars) too small and too close together to be houses or mobile homes. At the top of figure 6-51, at A, is the salvage yard office and workshop.

Most communities consider auto salvage yard operations to be eyesores. Therefore, they require auto salvage yard owners to shield their yards from direct view. In urban built-up areas most auto salvage yards are surrounded by high wooden fences. In rural areas, such as site 72, the yards are surrounded by trees. The shielding trees can be seen in figure 6-51 at B and in the ground-level photograph of figure 6-52 at A.

Figure 6-51.--Large-scale vertical photograph of auto salvage yard near Columbia, Mo.

Figure 6-52.--Ground photograph of auto salvage yard.

Site No. 45 (Auto Salvage Yard)
 Location: St. Robert
 Pulaski County, Missouri
 Geographic Coordinates: 37°48'N
 92°09'W

Figure 6-53 presents another example of an auto salvage yard. This yard is located near the Fort Leonard Wood U.S. Army base just west of the four-lane access road to the base. As with the previous example, notice how the autos are placed in tightly packed rows with dirt access roads. Also notice the sales office/workshop located at A.

Situated in a heavily wooded area, the yard is obscured from view, particularly from the access road. Notice how the owner/operator of the yard is clearing some of the trees near B to make way for more wrecked or junked autos.

Figure 6-53.--Auto salvage yard at Fort Leonard Wood, Mo.

Site No. 7 (Sports Stadium)
 Location: St. Louis
 St. Louis City, Missouri
 Geographic Coordinates: 38°38'N
 90°12'W

Commercial sports complexes such as stadiums, field houses, racetracks, and other recreational complexes such as amusement parks and golf-course clubhouses are included in land use category 12. Such complexes are characterized by well-organized grounds and/or structures with ample parking facilities. Most of the larger complexes, such as sports stadiums, are located near major traffic access routes in metropolitan areas.

Site 7, Busch Memorial Stadium in downtown St. Louis, is typical of sports complexes included in land use category 12. Figure 6-54 shows a sports stadium with parking facilities at A and major traffic access routes at B.

Figure 6-55.--Ground photograph of Busch Memorial Stadium.

Site No. 78 (Sports Stadiums)
 Location: Kansas City
 Jackson County, Missouri
 Geographic Coordinates: 39°03'N
 94°29'W

The Harry S. Truman Sports Complex, figure 6-56, is a unique twin sports stadium located on the east side of the Kansas City Metropolitan area at the junction of Interstate 70 and the I-435 bypass. The baseball stadium at A is the home of the Kansas City Royals; the football stadium at B is the home of the Kansas City Chiefs. Notice the extensive area of parking surrounding the stadiums. Also notice the additional parking facilities at C, which have been added since completion of the complex.

As with all major sports complexes, ease of traffic access is very important. Notice the numerous parking access points at D.

Figure 6-54.--Busch Memorial Stadium in downtown St. Louis, Mo.

Also notice at C the pedestrian walkways extending to the stadium at C from the parking facilities. The stadium, which seats over 50,000, is the home for professional football, baseball, and soccer teams.

This sports facility in the downtown area of St. Louis is surrounded by many open air parking facilities. These facilities are also used by the people employed in the area during the weekdays. Multistoried parking facilities developed in the area, however, they are very difficult to identify on the photography.

Figure 6-55 shows the walkramps to the stadium.

Figure 6-56.--Small-scale photograph of Harry S. Truman Sports Complex, Kansas City.

Figure 6-57 is a large-scale photograph of the sports complex. Notice the walkramps for both the baseball stadium at the top of the photograph and the football stadium in the foreground. The VIP parking area is shown at A. The dark circular areas surrounding the football stadium are shrubbery areas. Also notice the lighter strips on the football field. At the time of this photograph (June 1980) the artificial turf was under repair.

Figure 6-57.--Low-level oblique photograph of sports complex.

Figure 6-58 presents a ground-level view of the sports complex--the football stadium on the left, and the baseball stadium on the right. Notice the spiral walkramp at A.

Figure 6-58.--Harry S. Truman Sports Complex.

Site No. 59 (Regional Fairgrounds)
Location: Springfield
Greene County, Missouri
Geographic Coordinates: 37°15'N
93°18'W

Fairgrounds, including associated exhibition buildings, grandstands, racetracks, rodeo arenas, corrals, paddock areas, and midway areas are included in land use category 12. Circled in figure 6-59 is the Ozark Empire Regional Fairgrounds in east Springfield. Originally located away from the Springfield urbanized area, urban encroachment is quite evident in this small-scale photograph. Notice residential structures to the south, Central Bible College to the east, and Hillcrest High School to the north. Figure 6-59 also shows Dickerson Park Zoo, west of the fairgrounds.

Figure 6-59.--Mapping photograph of Ozark Empire Regional Fairgrounds at Springfield.

The facilities associated with this regional fairground area are shown more clearly in figure 6-60. Exhibition buildings are located at A, the racetrack at B, the midway area at C, and the grandstand at D. Notice the lack of parking facilities at the fairgrounds.

Figure 6-60.--Large-scale photograph of Ozark Empire Fairgrounds.

Figure 6-61 shows one of the exhibition buildings at the fairgrounds.

Figure 6-61.--Exhibition building at Ozark Empire Fairgrounds.

Site No. 5 (Hospital)
 Location: St. Louis
 St. Louis City, Missouri
 Geographic Coordinates: 38°38'N
 90°16'W

Medical and health facilities, such as Barnes Hospital in figure 6-62 are included in land use category 12. Since this particular site is adjacent to other Commercial and Services structures it is difficult to identify the site as a medical complex from aerial photographs. One must rely on ancillary data or ground investigations to identify the site as a hospital.

Some features which should be noted in figure 6-62 are the parking facilities at A, the underground parking facilities at B (where the tennis courts are located), and the interconnecting walkways between the buildings such as those at C.

Figure 6-62.--Low-level oblique photograph of Barnes Hospital in St. Louis, Mo.

Pictured in figure 6-63 is a ground-level photograph of the Barnes Hospital complex. Notice the interconnecting walkways at A.

Figure 6-63.--Barnes Hospital, St. Louis, Mo.

Site No. 57 (Hospital)
 Location: Springfield
 Greene County, Missouri
 Geographic Coordinates: 37°11'N
 93°17'W

Figure 6-64 depicts another regional medical complex--Springfield's St. John's Hospital serving southwest Missouri. Unlike Barnes Hospital in St. Louis, this medical complex is more easily identified since it is surrounded by residential structures. As with most medical complexes, the multistory buildings and wings are interconnected. Prominent in figure 6-64 is the main entrance to the hospital with the circular drive and covered entrance. A more recent addition to the hospital--an east wing--is shown at A. Ample parking is available at B.

A ground-level view of the hospital is shown in figure 6-65. Notice the cross on top of the complex at A, and the newer wing at B.

Figure 6-64.--Forward oblique photograph of St. John's Hospital in Springfield, Mo.

Figure 6-65.--St. John's Hospital,
Springfield, Mo.

Figure 6-66.--Mapping photograph of Federal
Medical Center at Springfield, Mo.

Site No. 56 (Federal Hospital)
Location: Springfield
Greene County, Missouri
Geographic Coordinates: 37°10'N
93°19'W

Federal and State prisons and medical-correctional institutional areas are also included in land use category 12. Figure 6-66 identifies the Federal Medical Center in southwest Springfield. Once located away from the built-up area, urban expansion has produced residential encroachment.

Even though there has been residential encroachment in the area around the institution, there will be maintained a clean buffer zone between the institution and the nearest built-up area.

The Federal Medical Center is a minimum security complex devoted primarily to mental health care and incarceration of individuals convicted of "white-collar" crimes.

Figure 6-67 provides a clearer view of many of the photorecognition characteristics associated with such an institution. Note the double chain link fence at A, the guard towers at B, and the structural similarity of the buildings at C. Also notice the baseball field at D. This particular area is enclosed by yet another wall (point E). A more secure area of the institution is shown at F. Employee and visitor parking facilities are shown at G.

Institutions such as this normally maintain some of their own fuel and water. Behind the double chain link fence to the west is a water tower at H and a storage tank at I. Also visible is a maintenance building at J.

The main entrance to the institution is shown in figure 6-68. Notice the guard tower at A.

Figure 6-67.--Large-scale vertical
photograph of Federal Medical Center.

Figure 6-68.--Main entrance to Federal
Medical Center at Springfield, Mo.

Site No. 58 (University)
 Location: Springfield
 Greene County, Missouri
 Geographic Coordinates: 37°12'N
 93°16'W

All buildings, grounds, and parking lots associated with educational institutions are included in land use category 12. The physical layout of Southwest Missouri State University in Springfield is shown in figure 6-69. Identified in this stereogram are the football stadium at A, tennis courts at B, newer, high-rise dormitories at C, and older classroom buildings at D. Note the relative height differences between the high-rise dormitories at C and the older classroom buildings at D.

Figure 6-69.--Stereogram of Southwest Missouri State University campus in Springfield, Mo. (Note that this photograph is oriented with east at top.)

A large-scale vertical photograph of the campus is shown in figure 6-70. Again, note the football stadium at A, the tennis courts at B, and the high-rise dormitories at C. Also note the availability of parking at D. This photograph was taken in July 1980. Had it been taken during the fall or spring, the parking lots would have been full. Other facilities visible in figure 6-70 include the gymnasium and swimming pool at E, the library at F, the student union at G, and the administration building at H. Finally, note the maze of walkways which link the campus structures.

Also shown in figure 6-70 is a practice field at I. Although it is unlikely, these areas may also fall victim to construction someday.

Figure 6-71 presents a ground-level view of Carrington Hall--the administration building on campus.

Figure 6-70.--Low-altitude vertical photograph of Southwest Missouri State University campus in Springfield, Mo.

Figure 6-71.--Administration building at Southwest Missouri State University.

Site No. 6 (Intermediate School)
 Location: Webster Groves
 St. Louis County, Missouri
 Geographic Coordinates: 38°34'N
 91°22'W

Elementary and secondary schools are most frequently located in residential neighborhoods

away from high traffic-volume areas. As with other institutional land uses, scholastic buildings, grounds, and associated facilities are included in land use category 12.

Elementary schools usually consist of one building with limited recreational facilities. Junior high schools may consist of several buildings and may even have their own football field or stadium. Intermediate and high schools, however, can be characterized as rather large campuses with several separate buildings (normally connected by covered walkways) or with interconnected buildings, large football/athletic fields with viewing stands, and parking facilities for the faculty and staff as well as for the students.

Figure 6-72 is a mapping photograph of Webster Groves Intermediate School southwest of St. Louis. The intermediate school is shown at point A. At point B can be seen a municipal park and recreation area--two ballfields, a swimming pool, and some tennis courts. This latter area should be classified as land use category 17. Also shown in figure 6-72, just north of the school, is Interstate 44.

Figure 6-72.--Small-scale photograph of intermediate school campus and municipal park and recreation area, Webster Groves, Mo.

Figure 6-73.--Large-scale vertical photograph of Webster Groves Intermediate School.

Figure 6-73 is a vertical photograph of the intermediate school campus. The school building is shown at A, the football/athletic field at B, and faculty parking facilities at C. Also notice the controlled traffic access at D.

The front entrance to the school and covered passenger loading and unloading area are shown in figure 6-74.

Figure 6-74.--Main entrance and passenger loading area for Webster Groves Intermediate School.

Site No. 48 (Military Installation)
Location: Fort Leonard Wood
Pulaski County, Missouri
Geographic Coordinates: 37°46'N
92°08'W

Figure 6-75 shows several key identification features of most military installations. Point A identifies the main parade ground. Although this particular site is not surrounded by buildings on all sides, most military base parade grounds are surrounded by administrative buildings. Point B, site of the original parade grounds, is now an athletic field. Basic training quarters and instructional buildings are shown at C. On-base, dependent housing facilities are shown at D. A general merchandise warehouse area can be seen at E. Also shown at F is the airfield which serves the base. Point G identifies advanced training barracks and training buildings. Although not shown on this photograph, firing ranges and bivouac areas are located just to the south.

Figure 6-76 presents a large-scale photograph of the main parade grounds at A, the basic training building at B, the base training barracks at C, the base theater at D, and athletic fields at E. Notice the viewing stands on the west side of the parade grounds. Also note the whitish tone of the training area at B where the recruits have denuded the area.

Figure 6-75.--Mapping photograph of Fort Leonard Wood Army base.

Figure 6-76.--Low-level oblique photograph of main parade grounds and basic training facilities at Fort Leonard Wood, Mo.

Category 13--Industrial

Category Description. Probably no other category in the classification system has such a diversity of structure types as the industrial category. This category covers a wide variety of land uses, from installations involved with product design, assembly, finishing, processing, and packaging to steel mills, cement plants, chemical plants, electric power generators, oil refineries, and mining. In all of these industrial activities, the buildings, parking and shipment areas, and stockpiles of raw materials and waste products are all included in the delineation of the area. For mining, only the surface manifestation of the mining is delineated. That is, the

buildings, mine shafts, and spoil material are included. Underground mining activities are not delineated as industrial but rather are shown by the type of surface cover (i.e., agricultural land, forest land).

Different classification systems separate industries into different sub-categories in a variety of ways. The Standard Industrial Classification Manual, for example, describes industrial categories by the generic type of industry as listed below:

- Division A - Agriculture, forestry, and fishing
- Division B - Mining
- Division C - Construction
- Division D - Manufacturing

Many metropolitan areas use this classification scheme; however, there are several other schemes used to classify industries (processing industries, manufacturing industries, and fabrication industries). Industries, by whatever classification term is used, have identification features unique to each type. Professional Paper 964 (Anderson and others, 1976) only used the term "industrial;" however, in the descriptive text, it refers to a breakout of light and heavy industries.

To illustrate the difference between light and heavy industries, the following descriptions have been used.

Light Manufacturing. "These light industrial activities are focused on design, assembly, finishing, and packaging of products rather than processing of raw materials. Materials used have generally been processed at least once. Included are facilities for administration and research, assembly, storage and warehousing, shipping, and associated parking lots and grounds. Land held in reserve may also be evident. Among the industries in this category are research laboratories, small textile mills, electronics firms, trucking companies, and even such large industries as automobile assembly plants.

"In comparison with heavy industries, these are relatively 'clean'--contributing considerably less smoke, noise, dust, other effluents, and visual 'pollution.'

"Identification of these industries can be based on type of buildings, parking and shipping arrangements, and location in relation to cities or villages. Unlike shopping centers, large commercial establishments or schools, outdoor storage of materials may be discernible along with trailer trucks parked on the premises. Rail lines may be present. Loading docks and power sources (large transformers, power lines, smokestacks, or large

fuel storage tanks) may suggest a manufacturing process rather than retail sales.

"Occasionally, inactive plants are found. Some have been converted to other uses such as retail sales. Where these uses could be detected, they were mapped accordingly. Otherwise, inactive plants are classified by their apparent former use."¹

Heavy Manufacturing. These industrial activities may be thought of as dirty, being devoted to heavy fabrication, making and assembling parts which are, in themselves, large and heavy, or to the processing of basic raw materials, including ore dressing operations.

The following description of heavy processing industries is taken from the Manual of Photographic Interpretation.

"Processing industries subject to accumulated raw materials to treatment by mechanical or chemical means or by heat to render them suitable for further processing, or to produce materials from which finished products can be made. Characteristic facilities for storing and handling bulk materials are useful clues to the identity of these industries. Blast furnaces, kilns, chemical processing towers, and large chimneys or stacks are usually visible and serve to indicate the kind of processing being carried on.

"Processing industries usually require large quantities of power; coal piles, fuel tanks, boiler houses, or transformer yards may indicate the source of power. The buildings which house processing equipment are often large and usually complex in outline and roof structure. Since processing usually includes refinement of raw materials, piles and ponds of waste are common; they have to be distinguished from stored raw materials.

"Processing industries can be subdivided according to function into mechanical processing, chemical processing, and heat processing industries. A few industries depart from the functional classification, but this departure does not interfere with the utility of the key.

"Mechanical processing industries are those engaged in sizing, sorting, separating, or otherwise changing the physical form or appearance of the raw materials. They can be identified by the presence of bulk materials stored in piles, ponds, or reservoirs, outdoor equipment such as silos, bins, bunkers, and open tanks, or handling equipment such as conveyors, launders, cranes, and railroad cars. A great deal of power is generally required, and boiler houses or transformer yards are

quite common. Buildings are likely to be large and complex. Piles or ponds of waste are also common.

"Mechanical processing industries differ from other processing industries in that they have few pipelines, closed or tall tanks or stacks except those on boiler houses. They do not have kilns.

"Typical mechanical processing industries are ore reducers, sawmills, and grain mills. Plants for hydroelectric power production, water purification, and sewage disposal also fall in this class. Aluminum refining is one of those industries whose images place them in this class although the processes are not mechanical.

"Chemical processing industries separate or rearrange the chemical constituents of the raw materials. Pressure, heat, and catalysts or other chemicals are usually employed. Closed vessels for handling liquids, gases, or suspensions of solids in liquids or gasses are typical of these industries, as is the use of fluid flow in processing. Closed tanks, pipelines, and towers for cracking or distillation are usually visible in photographs of chemical processing industries.

"Heat processing industries refine, separate, or reform the raw materials, or derive energy from them. Large quantities of coal or other fuel, chimneys, stacks, blast furnaces, and kilns are characteristic of these industries. Pipelines and tanks are sometimes used but are never abundant, and their presence, which might be taken to indicate chemical processing, is outweighed by the abundance of objects evidencing the use of heat. Industries typical of this class are thermal electric power plants, iron and copper smelters, cement plants, and clay products plants."²

Environmental Considerations. Industrial land use category (13) contains the greatest number of potential sources of pollution. Environmental problems can arise from the open storage of raw materials, the manufacturing of the products, the storage of the finished products and byproducts, and the disposal of waste materials.

The most frequent environmental impact is the deterioration of water quality and soil contamination. These conditions occur because of runoff from the raw materials, improper or careless storage practices for finished products, and improper disposal of harmful waste byproducts.

²The description of heavy processing industries is taken from the Manual of Photographic Interpretation, American Society of Photogrammetry (1960), p. 701-702.

¹Description of light industry is taken from the Land Use and Natural Resource Classification Manual (Swanson, 1972), p. 14-15.

Open storage of raw materials can lead to runoff containing heavy metals, phosphates, and other harmful substances which can find their way into surface and ground-water resources. Contamination from finished products can occur from faulty and leaking storage tanks, unrevetted storage tanks, and careless cleanup practices when a spill or leakage occurs.

The most damaging conditions which occur are the result of improper disposal of waste byproducts. Burying of drums containing toxic chemicals in unsafe landfills; directly discharging toxics into waterways or onto the ground; and unlined, poorly constructed waste lagoons all contribute to the deterioration of both ground and surface water quality.

At the local level, industries also contribute to air and noise pollution. Depending on the type of industry, the air quality in the surrounding area may deteriorate. Some of the air pollution is caused by auto emissions from employee autos and company trucks. Additional air quality problems may arise if the industry uses processes which require the emission of pollutants into the air.

Noise pollution by industry is generally confined to the plant and immediate area, effecting mostly those employed by the industry and nearby residents.

Interpretation Keys. The following examples illustrate various types of industry. These examples by no means cover all the various industrial types, but they do present a good cross section of the Industrial category.

Site No. 8 (Rolling Mills-Steel)
 Location: St. Louis
 St. Louis City, Missouri
 Geographic Coordinates: 38°37'N
 90°18'W

This site is an example of a steel rolling mill. The installation would be classified as a heavy or processing industry if compared to the definitions given in the category description. The stereogram, figure 6-77, shows the plant layout, the high-sided buildings, and the raw materials yard.

These types of mills have stacks along the sides of one of the buildings (point A, figure 6-78) which are probably soaking pits where the ingots of metal are heated to the point where the rolling process can form the required steel pieces.

Figure 6-77.--Stereogram of a steel rolling mill, St. Louis, Mo.

Figure 6-78.--Large-scale vertical photograph of building layout and stacks, St. Louis, Mo.

The identifying features of this type of installation are the long, high-sided buildings with the skylights (figure 6-79). The buildings are constructed in this manner to allow room for the heavy travelling cranes. These cranes move the steel to various processing stations within the buildings.

This installation is serviced by both truck and railroad. There is marked difference in the plant as shown in the small-scale stereogram, dated 1974, (figure 6-77) and the large-scale oblique photograph taken in 1980 (figure 6-80). In figure 6-80, tanks have been removed from A. Lack of raw materials in the

raw materials yard, point B, and absence of finished products would lead one to believe that the mill is no longer active.

Figure 6-79.--Ground photograph of high-sided building with skylights.

Figure 6-80.--Low-altitude oblique photograph of steel mill.

Site No. 9 (Barge Building)
 Location: St. Louis
 St. Louis City, Missouri
 Geographic Coordinates: 38°32'N
 90°15'W

This installation is located on the St. Louis waterfront south of mid-town (figure 6-81).

Figure 6-81.--Barge building and repair, St. Louis, Mo.

This installation is a barge-building and barge-repair or refitting operation. There are several identifying features for this installation. Among these are the number of barges in proximity to the installation. The barges are not moored in any systematic manner as they would be if they were being loaded or unloaded.

The primary identifying features of this type installation are shown in figure 6-82. Notice the shipways (marine railings) which are used to launch the vessels at A. The barge is built on the steel tracks, and when the hull is completed, it slides down the ways into the river. After the barge hull is launched, there remains a number of items to be completed, such as the decks and hatches. These jobs are generally completed while the barge is moored in the river. The travelling crane, point B, figure 6-82 and point A, figure 6-83, is used to move steel into position for welding during construction. The raw materials used in barge construction, steel, are shown in the form of rolls at point C, figure 6-82, and at point A, figure 6-84. Directly behind these rolls, at point B, figure 6-84, is a large building where fabrication of pieces of steel for the barges takes place.

In addition to the barges and tugboats moored next to the installation, there are two drydocks which are used to raise the vessel out of the water so that the hull is exposed for repair. At D, figure 6-82, is a tugboat in one drydock, being repaired or refitted.

This installation, although small in comparison to the large shipbuilding yards found in the major port cities, has the same identifying features. The size and length of the shipways will be larger in proportion to the size of the ship being constructed. The crane will be larger as will be the storage and fabrication areas. All of these identifying features will be recognized as a boat or shipbuilding area.

Figure 6-82.--Low-altitude oblique photograph showing plant components.

Figure 6-84.--Storage yard and fabrication building.

Site No. 21 (Cement Plant and Quarry)
 Location: Cape Girardeau
 Cape Girardeau County, Missouri
 Geographic Coordinates: 37°16'N
 89°32'W

Located near the southern city limits of Cape Girardeau, very near the Mississippi River, the plant shown in figures 6-85 through 6-89 has all of the recognition characteristics of a cement plant. Raw materials for the plant are obtained from the adjacent quarry shown in figure 6-85.

Figure 6-83.--Travelling crane.

Figure 6-85.--Cement plant with quarry, Cape Girardeau, Mo.

Since the quarry meets minimum size parameters (10 acres), it should be classified as category 75. The raw materials are transported from the quarry to a cement plant by means of a complex conveyor-belt system (figure 6-86).

Additional features associated with cement plants are identified in figures 6-87 and 6-88. Roasting kilns are shown at A in figure 6-87. Actually there are two kilns; however, one is obscured by the construction activity at C. Also shown at B in figure 6-87 are 10 large

silos. Several silos are shown in figure 6-88, as well as several cement trucks at A.

Figure 6-86.--Conveyor belts used for transporting materials to the plant area.

Figure 6-87.--Low-level photograph of cement plant.

Figure 6-88.--Ground photograph of silos and cement trucks.

Figure 6-89, presents a good view of the entire layout of the cement plant. Notice the quarry at A, the conveyor belts at B, storage silos at C, and the railroad at D. Although not shown on this photograph, port facilities are located just east of the plant area.

Figure 6-89.--Low-level oblique photograph of cement plant with associated features.

Site No. 35 (Mine)
 Location: Bunker
 Reynolds County, Missouri
 Geographic Coordinates: 37°32'N
 91°09'W

The primary purpose of the installation in figure 6-90 is to mine lead ore, process it, and concentrate it for smelting. This mining and the concentration processes that the ore is subjected to are generally the same for other mines in this area. Building arrangement and style of structures may be different; however, the identifying features will be the same. Identifying features of the mine are shown in figure 6-91: one or more shafts at A, an ore crusher building at B, and the concentration building at C. Since the mine uses water floatation, it has its own reservoir.

Figure 6-90.--Mapping photograph of a mining installation at Bunker, Mo.

Figure 6-91.--Mine shaft and processing building.

Figure 6-92 shows the plant layout. The reservoir is at A, the mine shafts at B, the crusher and concentrating buildings at D, and dewatering tanks at C. The processing buildings, built on a hillside, allow for gravity flow throughout the processing system.

All above-ground structures and features associated with mining activity, such as the reservoir, shafts, processing buildings, and tailings pond, should be included in category 13. Figure 6-93 shows the spatial relationship of these characteristics: point A--the reservoir, point B--the mine shafts and processing buildings, and point C, the tailings pond.

Figure 6-92.--The mine area, Bunker, Mo.

Figure 6-93.--Mine layout, Bunker, Mo.

Site No. 36 (Metal Processing)
 Location: Buick
 Reynolds County, Missouri
 Geographic Coordinates: 37°34'N
 91°08'W

This is a mine and ore concentration site. The final product from this mine is the same as that at site 35. This installation is larger than site 35 and the individual operations are separated. The tailings pond is rather far removed from the mine itself, as can be seen in figure 6-94, where point A is the mine and point B is the tailings pond.

The various components of the installation are connected by conveyors. The layout of the site is shown in figure 6-95. The mine shafts (A) at this mine do not look like the shafts at site 35, however, they serve the same purpose. The primary crusher (B) has a conveyor to the secondary grinder and screener (C) also shown at this operation. Also, there is a feed back to the primary crusher from the secondary grinder. The conveyor then moves the material to the silos (D) for storage awaiting the concentration process (E). The dewatering tanks are shown at F. Since this type of mining operation requires considerable electric power, a transformer yard was constructed at G. Point H indicates the location of piles of ore concentrate.

Figure 6-94.--Small-scale photograph of mine area.

Figure 6-95.--Mine layout indicating component points.

The ground photograph (figure 6-96) shows a close view of one of the mine shafts (A), the secondary grinder and screens (B), the storage silos (C), the concentrator and processing building (D), and the transformer yard (E). This mine, like site 35, is serviced by truck and railroad.

Figure 6-96.--Ground photograph of mine area, Buick, Mo.

Site No. 37 (Mine and Smelter)
Location: Buick
Reynolds County, Missouri
Geographic Coordinates: 37°34'N
91°08'W

Shown in figure 6-97 is the area covered by the mine, smelter, and tailings pond of a large new installation near Buick, Missouri.

Figure 6-97.--Mapping photograph of mining and lead smelting plant at Buick, Mo.

Figure 6-98 shows a low-level oblique photograph of the mining and concentrator area at A and the smelter area at B. The mining and concentration of lead ore were previously illustrated in sites 35 and 36. Therefore, the description given here is for the smelting area only.

The smelting areas are labeled in figure 6-99. The concentrate and flux begins the smelting process at A where the ingredients for smelting are mixed together. Then, by conveyor, they are transported to B, the sintering building. Sintered material is transported to C, the blast furnace. From the blast furnace the material moves into the refinery building at D. The lead bullion awaits shipment at E. Sulfuric acid is a byproduct of the smelting process. The fumes from the smelting process are piped through the bag house (F) to the acid plant (G) where they are converted to sulfuric acid.

Figure 6-98.--Low-level photograph of the mining and smelter areas.

Figure 6-99.--Low-level photograph of lead smelter.

Figure 6-100 shows a ground-level photograph of the mixing building (A), the smelting building (B), the blast furnace building (C), the refinery (D), and the stack for the bag house (E).

Figure 6-100.--Ground photograph of the smelter area at Buick, Mo.

Site No. 50 (Stave Company)
 Location: Lebanon
 Laclede County, Missouri
 Geographic Coordinates: 37°40'N
 92°40'W

Site No. 85 (Sawmill)
 Location: Potosi
 Washington County, Missouri
 Geographic Coordinates: 37°55'N
 90°51'W

These two sites are lumber-related industries and therefore will be considered together. Site 50 is a stave mill which, in addition to producing barrel staves, also produces walnut fixtures. The stave mill is located in the town of Lebanon (figure 6-101). The sawmill (site 85) is located in a heavily forested area (see figure 6-102) and also produces pallets.

Figure 6-101.--Mapping photograph of the stave company, Lebanon, Mo.

Figure 6-102.--Mapping photograph of the lumber mill near Potosi, Mo.

Raw materials for both plants are wood. However, the sawmill uses logs while the stave company uses processed lumber. Figure 6-103 shows lumber piles stacked at A and stave processing at B. Figure 6-104 identifies the location of the storage area for logs (B) to be processed at the sawmill (A).

The logs, before processing, are shown in the ground shot at A in figure 6-105, while the finished pallets are shown at B.

Figure 6-103.--Stave factory, Lebanon, Mo.

Figure 6-104.--Sawmill, Potosi, Mo.

Figure 6-105.--Sawmill and raw materials.

The one identifying feature which is identical for both of these industries is the sawdust burner. The sawdust burners for the stave factory can be seen in figure 6-106, while the sawdust burner for the sawmill is shown in figure 6-107.

Figure 6-106.--Sawdust burners at the stave factory, Lebanon, Mo.

Figure 6-107.--Sawdust burner at the lumber mill, Potosi, Mo.

Site No. 60 (Light Industry)
 Location: Springfield
 Greene County, Missouri
 Geographic Coordinates: 37°15'N
 93°12'W

This plant is located just east of Springfield, Mo., an area surrounded by cropland and pasture (figure 6-108). The features which identify light processing industries are large expansive flat top buildings with low profiles, ventilation outlets on the roof, and silos, at C, for storage of raw materials (figure 6-109). This installation is serviced by rail (A) and by truck (B). Truck loading docks are shown at E and F. The largest concrete apron and truck loading dock (E) is probably the shipping dock, while the railroad and truck loading docks at F are most likely used for delivery of raw materials. Also note the employee parking at D.

Figure 6-108.--Mapping photograph of light processing industry east of Springfield, Mo.

Figure 6-109.--Low-level oblique photograph of light industry.

Also notice in figure 6-110 the rail tank car at A. With light industry, the silos may not always be present, but the remaining identifying features will be.

Figure 6-110.--Ground shot of light industry building shows low profile, loading docks, and storage silos.

Site No. 66 (Dam-Hydroelectric)
 Location: Table Rock Reservoir
 Taney County, Missouri
 Geographic Coordinates: 36°36'N
 93°19'W

Site No. 71 (Nuclear Power Plant)
 Location: Reform
 Callaway County, Missouri
 Geographic Coordinates: 38°45'N
 91°45'W

Site No. 96 (Thomas Hill Power Plant-Thermal)
 Location: Thomas Hill Reservoir
 Randolph County, Missouri
 Geographic Coordinates: 39°33'N
 92°38'W

Sites 66, 71, and 96 are power plants. These sites represent the three major types of power generation plants: hydroelectric, nuclear, and thermal. Some of the identifying features are the same for all (transformer yards and transmission lines), while other identification features are unique.

Site No. 66 is a hydroelectric plant. Although there is machinery and equipment associated with this plant, it is housed within the dam. The identifying features associated with this industry are shown on figure 6-111, particularly the dam (A). The electrical generator area is identified by tailraces at B. The water in the reservoir is funneled past

a set of turbines which are rotated by water pressure. The turbines are in turn attached to generators for developing electric current. The transformer yard, at C, is a starting point for transmitting the electric current. In addition to using the dam as a means of generating electric power, the reservoir provides recreational activities. At D, a fish hatchery uses cold water from a reservoir.

Figure 6-111.--Table Rock hydroelectric power generation dam.

Site No. 71 is a nuclear power plant under construction. Figure 6-112, photographed in July 1980, shows the plant under construction. There are many features which can be used to identify a nuclear plant. Among these features are the cooling tower (A) and the nuclear reactor building (B). In this particular photograph, because these items are under construction, they are difficult to identify. Nuclear power plants require a source of cooling water (C) as do thermal power plants (site 96). In the nuclear plant, the nuclear reactor creates the heat to convert the water to superheated steam which drives the turbines which turn the generators. Prior to discharge, water must be cooled and purified for further use. The ground photograph (figure 6-113), taken in June 1981, clearly shows the cooling tower (A) and the nuclear reactor building (B).

Site 96 is a thermal power plant. Figure 6-114, taken on April 11, 1977, shows the plant prior to recent expansion. The plant is located next to a reservoir so that water needed for cooling is readily available. Also, note that it is located in an area where there is a great deal of surface mineable coal for fuel. Features which identify the installation

Figure 6-112.--Nuclear plant under construction near Reform, Mo., July 1980.

are shown in figure 6-115: the coal pile (A) to be used for fuel and the conveyor belt which transports the coal to the main plant (B and C). In the plant, the coal is put through tube or ball mills to grind it into a fine powder. This coal powder is used to fire the boiler which heats the water and converts it to steam to turn turbines that run the generators. The water is then cooled (D). Another identifiable feature is the transformer yard (E).

Figure 6-113.--Ground photograph of the same nuclear power plant, June 1981.

Figure 6-114.--Mapping photograph of thermal power plant at Thomas Hill Reservoir, April 1977.

The photograph in figure 6-115 was taken in 1981. Construction has produced a great deal of change since the time the photograph was acquired for figure 6-114.

Figure 6-115.--Low-level oblique photograph of the thermal power plant, 1981.

Site No. 81 (Stockyards)
 Location: Kansas City
 Jackson County, Missouri
 Geographic Coordinates: 39°06'N,
 94°37'W

This land use type (figure 6-116) is a unique type of industrial installation which does not exist to the extent of the others previously illustrated. If the installation was in the countryside, it probably would be confused with confined feeding category 23.

The installation is served by both railroad and highway. The rectangular pattern of stock pens at A, figure 6-117, is one of its identifying features. The buildings at B are also divided into pens; this can be clearly seen only from the ground (figure 6-118).

Figure 6-116.--Mapping photograph of the stockyards in Kansas City, Mo.

Figure 6-117.--Low-altitude oblique photograph of the stockyards in Kansas City.

Figure 6-118.--Ground photograph of stockyards.

Site No. 90 (Coal Processing Plant)

Location: Hartford

Putnam County, Missouri

Geographic Coordinates: 40°29'N
92°52'W

This coal processing plant, figure 6-119, is located in the coal surface mining area of northern Missouri. Its function is to receive the coal, crush it, and grade it into specific sizes. The coal is either mined nearby or trucked in from more distant areas for processing. At this installation, the coal is

Figure 6-119.--Low-altitude oblique photograph of a coal processing plant near Hartford, Mo.

Figure 6-120.--Low-altitude vertical photograph of processing plant, Hartford, Mo.

primarily obtained from the surface mine area at point A. At the plant, the coal is moved to the crusher house (figure 6-120), and transported by conveyors to various areas of the yard where it awaits shipment (figure 6-121) to truck loading chutes (B, figure 6-120).

Figure 6-121.--Coal in bin awaiting transshipment.

Site No. 100 (Chemical Plant)

Location: Louisiana

Pike County, Missouri

Geographic Coordinates: 39°41'N
91°19'W

This chemical plant, figure 6-122, is divided into various sections which constitute different types of processing. The features which identify this installation as a chemical plant are visible on both the large-scale photograph and the ground photograph. The fractionating towers may be seen in several areas of the plant (A, figures 6-122, 6-123, and 6-124). There are also cooling towers in each area of chemical processing (B, figures 6-122, 6-123, and 6-124). The various types of storage tanks, spherical and cylindrical, are seen throughout the plant (C, figure 6-122 and 6-123). Also visible is numerous piping used for specific processing, as well as for connecting the various parts of the plant. A coal-fueled power plant is located at D, figure 6-122. The plant is served by river, truck, and railroad, as shown at E in figure 6-122.

These Industrial category illustrations are but a few of the land use classification types in the State of Missouri, and represent the categories of light and heavy industry described in U.S. Geological Survey Professional Paper 964 (Anderson and others, 1976).

Figure 6-122.--Vertical photograph of the chemical plant at Louisiana, Mo.

Figure 6-123.--Fractionating columns and tanks.

Figure 6-124.--Fractionating columns and cooling towers.

Category 14--Transportation, Communications, and Utilities

Category Description. Major transportation routes and areas greatly influence other land uses. The types and extent of routes determine the degree of access and thus affect the present and potential use of an area.

Linear areas of highways and railroads are among the land use types included in this

category. The highways include rights-of-way, interchanges, and service and terminal facilities. Rail facilities include stations, parking lots, roundhouses, repair and switching yards, and related areas. Also included are overland track and spur connections of sufficient width for delineation at mapping scale.

Airports, seaports, and major lake and river ports are also included in this category.

Airport facilities include all the runways, intervening land, terminals, service buildings, navigation aids, fuel storage, parking lots, and limited buffer zones. Port facilities include docks, shipyards, drydocks, locks, and waterway control structures.

Finally, communications and utilities areas are included in this category. Communications and utilities areas are those involved with the processing, treatment, and transportation of water, gas, oil, electricity, and areas used for airwave communications. Included are pumping stations, electric substations, and areas used for radio, radar, or television antennas.

Environmental Considerations. Transportation facilities such as highways, railroads, airports, and riverports are potential water pollution sources. The pollution occurs as a result of runoff and leakage of fossil fuels associated with these facilities. River and lake ports have a high potential for pollution. Leakage and spillage of raw chemicals, petroleum products, coal, and other cargo handled and distributed in ports can be detrimental to water quality and aquatic life, and cause health problems for adjacent communities. Toxic substances such as polychlorinated biphenyl (PCB), used in diesel locomotive transformers and motors, are often stored at railroad yards and repair shops. The land around airport facilities is often used for solid waste disposal, creating a potential for soil and water contamination. Accidental discharge of toxic chemicals in transport via highways and railways can release these poisons to the soil, water, and air. The toxin can sterilize the soil, reduce air quality, and contaminate ground water. Almost all major transportation facilities, especially those with heavy traffic, are generally associated with unacceptable levels of noise and inferior air quality.

Waste-water treatment plants can be a major source of water pollution. Obsolete, inadequate, and overloaded facilities result in the discharge of effluents that do not meet water quality standards, and at times raw sewage may be discharged into the natural drainage system.

When ecologically sensitive areas such as wetlands and forestlands are altered, the whole ecosystem may be changed. Facilities associated with the distant transport of communications and electricity have rights-of-way clearing through forest and other natural areas which can also have adverse impacts on the environment. Rights-of-way are usually sprayed with pesticides and herbicides which can have a detrimental effect on wildlife and

contribute to water pollution by surface runoff.

Interpretation Keys. The following nine sites illustrate the land use types associated with the Transportation, Communications, and Utilities category.

Site No. 10 (Highway Intersection)
Location: St. Louis
St. Louis City, Missouri
Geographic Coordinates: 38°38'N
90°17'W

Figure 6-125 shows the intersection of U.S. Highway 40 and Hampton Avenue in St. Louis, Missouri. It is an excellent example of a major urban arterial road and a controlled-access highway. The cloverleaf-type intersections, dividing medians, and the right-of-way, are all included when delineating highways. However, they must meet the minimum width requirements of the land use and land cover specifications (300 feet wide for controlled-access highways). On the aerial photograph, the highway is easily recognizable by its lighter, smooth texture and ribbonlike appearance. The dividing medians between lanes are identified by their darker tone and position. The rectangular images on the road surfaces are cars and trucks.

Figure 6-125.--A low-level photograph of a highway cloverleaf, St. Louis, Mo.

Site No. 11 (Truck Terminal)
Location: St. Louis
St. Louis City, Missouri
Geographic Coordinates: 38°31'N
90°12'W

Truck terminals generally provide maintenance and serve as a transfer point for shifting loads between trucks. They are classified as category 14 whenever they meet minimum mapping size requirements. Such a truck terminal has been circled in figure 6-126. Notice its proximity to a major transportation route--Interstate 55--to its left. The transfer building is the long, narrow, white structure in the circle on the photograph. Near the top center of the circle at A is a smaller square maintenance and repair building.

Figure 6-126.--Mapping photograph of a truck terminal, St. Louis, Mo.

Truck terminal facilities can be seen more clearly in the vertical photograph shown in figure 6-127. Notice the transfer building at A, the maintenance and repair shop at B, and parking facilities at C. The volume of business activity at this terminal is reflected by the size of its parking space and the number of trailers parked at the transfer building.

Figure 6-127.--Truck terminal, St. Louis, Mo.

Site No. 12 (Railroad Yards)
Location: St. Louis
St. Louis City, Missouri
Geographic Coordinates: 38°35'N
90°12'W

Rail facilities in this land use category include stations, roundhouses, repair shops, switching and storage yards, and related areas, as well as surface track and spur connections of sufficient width for map delineation.

Rail facilities circled in figure 6-128 are representative of those in land use category 14. Often single- and double-track railroad beds are too narrow for delineation on small-scale land use maps.

Figure 6-128.--Mapping photograph of rail facilities, St. Louis, Mo.

The southern choke-point for these yards is shown at point A in figure 6-129. The choke-point is that point in the yards where the main line branches out into the rail yards. Figure 6-129 also shows related rail facilities (switching and storage yards at B, repair shops at C, and a warehouse at D). Notice the tracks entering the repair shops. At D, notice the truck trailers backed up to the warehouse loading docks (docks not visible).

Figure 6-129.--Low-level oblique photograph of rail facilities on St. Louis waterfront.

Railroads, with their yards, tracks, and repair facilities, are easily recognized by their linear pattern. The yards all emanate from a choke-point on the main tracks, the

spurs usually parallel storage buildings, and repair shops have tracks entering or running through them.

Site No. 61 (Railroad Yards and Repair Shops)

Location: Springfield

Greene County, Missouri

Geographic Coordinates: $37^{\circ}13'N$
 $93^{\circ}20'W$

Figure 6-130 presents another view of a railroad yard with repair shops. As with site 12, this railroad facility exhibits the common photorecognition characteristics--a widening area of parallel tracks emanating from a choke-point on the main tracks, large repair buildings with tracks entering the structures, and an irregular track pattern in the repair area of the railroad yard.

Figure 6-130.--Mapping photograph of the railroad yard at Springfield, Mo.

Figure 6-131.--Low-altitude oblique photograph of the switching yard and repair shops.

Site details are seen in figure 6-131. Located at Springfield, the site is part of the Burlington Northern railroad line. Repair shops are located at A, while the main switching and car storage area is at B. Notice the irregular track pattern of the repair area. The repair shop and employee parking lot are shown from ground level in figure 6-132.

Figure 6-132.--Burlington Northern diesel repair shop.

Site No. 42 (Airport)

Location: Vichy

Maries County, Missouri

Geographic Coordinates: $38^{\circ}08'N$
 $91^{\circ}46'W$

Airports, with their runways, hangars, shops, and associated facilities, are included in land use category 14. Airports vary in size from grass landing strips to vast complexes in urban areas. The key identifying photographic feature of an airport is an area cleared of vegetation and other obstructions and with long, linear runway surfaces. If the airport is more than just a grass landing strip (which are not shown on 1:250,000-scale U.S. Geological Survey land use and land cover maps), it will normally have smaller parallel taxi strips, aircraft parking aprons, hangars, and passenger terminals. The primary runways are normally oriented into the prevailing wind.

Figure 6-133 is a stereogram of the Rolla National Airport at Vichy. This stereoscopic image illustrates level terrain of the airport.

The airport's primary function is to provide maintenance and storage facilities for general aviation aircraft. Charter flights are also common; however, at the time of this writing, there were no scheduled commercial flights. This accounts for the lack of large terminal buildings and other built-up facilities in figure 6-134. The main runways are located at A and B, the main hangars at C, and taxi strips at D.

Figure 6-135 shows three DC-3 aircraft parked in front of one of the main hangars.

Figure 6-133.--Stereogram of airport at Vichy, Mo.

Figure 6-134.--Low-level oblique of Rolla National Airport at Vichy, Mo.

Figure 6-135.--DC-3 aircraft parked on apron at Rolla National Airport, Vichy, Mo.

Site No. 62 (Downtown Airport)
Location: Springfield
Greene County, Missouri
Geographic Coordinates: 37°13'N
93°15'W

Figure 6-136 shows the Springfield Downtown Airport. Like most downtown airports, open areas which once surrounded the facility are now occupied by residential (A) or commercial structures (B). Frequently, these airport facilities are abutted by other land use categories. As residents become more and more concerned about potential aircraft accidents, more attempts are made to close the facilities.

Figure 6-136.--Mapping photograph of Downtown Airport, Springfield, Mo.

Figure 6-137, depicts the single paved runway at A, taxi strip at B, parking aprons (grass rather than hard surface), and hangar facilities at C.

Figure 6-137.--Downtown airport, Springfield, Mo.

Site No. 14 (Municipal Water Treatment Plant)
Location: St. Louis
St. Louis City, Missouri
Geographic Coordinates: 38°45'N
90°11'W

One of the two municipal water treatment plants in St. Louis, Missouri, is pictured in figure 6-138. This plant, the Chain of Rocks Waterworks, uses the Mississippi River for its water source. The water is pumped into settling tanks where, after a period of time, heavier particulate materials and impurities settle out. Later the water is filtered, chlorinated, and then distributed to the city's water mains. The settling tanks and water treatment areas are more clearly shown in figure 6-139. The settling tanks appear as the larger rectangular tanks at A, the water treatment tanks are square tanks at B, and the treatment plant is shown at C.

Figure 6-138.--Mapping photograph of Chain of Rocks Waterworks in St. Louis, Mo.

Figure 6-139.--Oblique photograph of Chain of Rocks Waterworks.

Figure 6-140 presents a ground-level photograph of the settling tanks in the foreground with the treatment plant in the background.

Figure 6-140.--Ground-level photograph of Chain of Rocks Waterworks.

Site No. 63. (Water Treatment Plant)
 Location: Springfield
 Greene County, Missouri
 Geographic Coordinates: 37°10'N
 93°13'W

This plant, just newly constructed, supplements the supply of water provided by the plant at Fullbright Spring. The water for the plant is pumped from the James River, treated, then pumped into the city's water mains. The low-level vertical photograph shown in figure 6-141 was taken in July 1980, near the final phases of construction. Notice the rectangular shape of the treatment tanks.

A visit to the site in January 1981 revealed that the plant had been placed in operation (see figure 6-142).

Figure 6-141.--Water treatment plant under construction, July 1980, Springfield Mo.

Figure 6-142.--Water treatment plant in operation, January 1981, Springfield, Mo.

Site No. 13 (Sewage Treatment Plant)
 Location: Lemay
 St. Louis County, Missouri
 Geographic Coordinates: $38^{\circ}32'N$
 $90^{\circ}17'W$

Site No. 91 (Sewage Treatment Plant)
 Location: Kirksville
 Adair County, Missouri
 Geographic Coordinates: $40^{\circ}09'N$
 $92^{\circ}34'W$

Sewage treatment plants are found in or around most medium or large cities. There are many different processes by which sewage can be treated, however, the identifiable features are nearly the same for all plants.

Site 13, figure 6-143, shows a sewage treatment plant for St. Louis City prior to expansion. The array of rectangular tanks is a typical identifying feature. The large-scale oblique photograph (figure 6-144), taken June 1980, shows the expanded plant. There are two types of tanks visible in this photograph; initial processing tanks are shown at A and

Figure 6-143.--Small-scale photograph of St. Louis sewage treatment plant, 1974.

secondary tanks are shown at B. The tanks at C are newly constructed and were not in operation at the time of the photograph (June 1981).

Figure 6-144.--Low-altitude oblique photograph (1980) of sewage treatment plant undergoing additional construction, St. Louis, Mo.

Site 91 is a small sewage treatment plant just south of Kirksville, Missouri. The plant has circular tanks, as opposed to the rectangular tanks at site 13. Figure 6-145 shows the plant layout and several identifying features. Point A is the area of initial processing where the screening and grinding of raw sewage occurs. At B are two primary settling tanks. The tone of the liquid in the tanks is a clue to the process flow. The darker tanks at C contain water which has been treated, while the lighter tanks at B hold raw sewage. The two circular white tanks at D are probably digester tanks where the material that settles out by the settling process is converted to sludge. Point E is the outlet where the treated effluent flows into a nearby stream.

Figure 6-145.--Low-altitude oblique photograph of sewage treatment plant, Kirksville, Mo.

Category 15--Industrial and Commercial Complexes

Category Description. The Industrial and Commercial Complexes category includes those industrial and commercial land uses that typically occur together or in close functional proximity. These areas are commonly referred to as "Industrial Parks." The major types of business establishments located in these planned industrial parks are light manufacturing, printing, distributing, research and development facilities, and computer systems companies, in addition to warehousing, wholesaling, and retailing.

Environmental Considerations. Industrial and Commercial Complexes are a minimum source of pollutants. The clean industries and commercial establishments in these "parks" generally are nonpolluting types. However, improper disposal of wastes and spillage of working materials will produce adverse environmental effects. Excessive surface water runoff from buildings and hard-surfaced parking areas creates the potential for flash flooding.

Interpretation Keys. Areas which meet specifications for Industrial and Commercial Complexes are not widespread. The following example, however, is representative of land use category 15.

Site No. 15 (Industrial and Commercial Complexes)

Location: Robertson
St. Louis County, Missouri.

Geographic Coordinates: 38°46'N
90°23'W

The photograph at figure 6-146 shows an industrial/commercial area just north of Lambert-St. Louis Airport. The buildings are modern in design with ample parking for employees. The warehouse and manufacturing buildings are serviced by railroad for transportation of raw materials and finished products. The ground photograph, figure 6-147, provides a closeup of one of the buildings and the well-kept grounds.

Industrial and Commercial Complexes are usually located in suburban or rural areas. The key identifying feature is the planned layout of buildings exhibiting the same or very similar construction. The lack of smokestacks, storage tanks, raw materials or finished products, and wastes signifies that no heavy industries are present.

Figure 6-146.--Low-altitude oblique photograph of an Industrial and Commercial Complex, St. Louis County, Mo.

Figure 6-147.--Ground photograph of Industrial and Commercial Complex.

Category 16--Mixed Urban or Built-up Land

Category Description. The Mixed Urban or Built-up Land category is used when a mixture of urban uses cannot be separated into individual categories at mapping scales. Where more than one-third intermixture of another use or uses occurs in a specific area, it is classified as Mixed Urban or Built-up Land. This category includes developments along transportation routes and in cities, towns, and built-up areas where separate land uses cannot be mapped individually at map scale.

Environmental Considerations. This category, a mixture of urban land uses, such as residential, industrial, and commercial has the same potential for pollution as the land use categories which comprise it. Excessive runoff can affect water quality and produce a potential for flooding during heavy rainfalls.

Air quality and noise levels can be affected by this land use category as well.

Interpretation Keys. The following are examples of Mixed Urban or Built-up Land category 16.

Site No. 16 (Mixed Urban or Built-up Land)
Location: St. Louis
St. Louis City, Missouri
Geographic Coordinates: 38°38'N
90°15'W

Figure 6-148, an urban area east of Forest Park is an excellent example of Mixed Urban or Built-up Land. This site has several hotels and motels, apartments, duplexes, hospitals, schools, churches, office buildings, and other commercial activities. The main land uses are commercial and residential, but in areas where more than one-third is mixed, it is classified as Mixed Urban or Built-up Land.

The oblique photograph in figure 6-149 shows height of the buildings, irregular building pattern, rectangular streets, and various sizes and shapes of the buildings. The key identifying feature of Mixed Urban or

Figure 6-148.--Mapping photograph of Mixed Urban or Built-up Land area, St. Louis, Mo.

Figure 6-149.--Low-altitude oblique photograph of Mixed Urban or Built-up Land area.

Built-up Land is its combination of both residential and commercial structures.

Site No. 64 (Mixed Urban or Built-up Land)
Location: Springfield
Greene County, Missouri
Geographic Coordinates: 37°12'N
93°17'W

Figure 6-150 shows an example of the Mixed Urban or Built-up Land in Springfield. This area is adjacent to the central business district; the small lighter tones and images are single-family residences or duplexes. The residential and commercial categories are too small to separate at the mapping scale; therefore, the area should be classified as a "mixed" category. On the small-scale mapping photograph (figure 6-150) it is evident that the "mixed" category is a transitional category between residential and commercial.

Figure 6-150.--Mapping photograph of a Mixed Urban and Built-up Land area, Springfield, Mo.

The large-scale photograph (figure 6-151) shows the complex intermixture of the various sizes and shapes of the buildings which make up this category.

Figure 6-151.--Large-scale photograph of Mixed Urban and Built-up Land area.

Category 17--Other Urban or Built-up Land

Category Description. Other Urban or Built-up Land consists of such land uses as parks, cemeteries, waste dumps, water control structures and spillways, golf courses and driving ranges, and undeveloped land within the urban area.

Environmental Considerations. Landfills are the main potential pollution sources in this category. Uncontrolled waste dumps are becoming obsolete since most communities dispose of waste in sanitary landfills or recycle it. (Note that sanitary landfills are classified as land use category 76 rather than 17.) Parks, public lands, golf courses, zoos, and undeveloped land all provide open areas which for the most part are nonpolluting.

Interpretation Keys. The next four sites are land use examples included in category 17.

Site No. 17 (Forest Park)

Location: St. Louis

St. Louis City, Missouri

Geographic Coordinates: 38°38'N
90°17'W

Key recognition features of parks are irregular road patterns, the coarse photographic texture which results from tree cover, and various athletic fields. Larger parks usually have a pond or lake, while others have museums and bandstands. Urban parks are usually surrounded by residential or commercial areas.

Figure 6-152, Forest Park in St. Louis, illustrates a large urban park in a metropolitan area. It is a good example of this category. There is a diversity of activity visible within the confines of the park. In this photograph are parking lots (A), ball diamonds (B), tennis courts (C), golf courses (D), a zoo (E), and the Muny Opera (F) with its separate parking lot and seating area.

This site is indicative of the larger metropolitan parks. There are, however, smaller parks throughout the State in the medium and small towns which do not have all of the activities associated with them that the larger parks have. Many times without auxiliary source material, the park area may appear as a grove of trees and not be discernible as a park. Since most parks are generally surrounded by built-up area, by definition, they will generally fall in this category.

Figure 6-152.--Mapping photograph of Forest Park in St. Louis, Mo.

In the vertical photograph of figure 6-153 can be seen the zoo with its animal shelters, enclosures, aquatic animal ponds, and walkways between the different exhibits.

Figure 6-153.--Large-scale photograph of the St. Louis Zoo.

Site No. 47 (Golf Course)

Location: Fort Leonard Wood

Pulaski County, Missouri

Geographic Coordinates: 37°44'N
92°05'W

Golf courses are also included in the Other Urban or Built-up Land category. Often they are located within urban areas, in parks, and on outskirts of suburban residential areas.

If the golf course is part of an athletic complex, the built-up area consists of the clubhouse, swimming pool, and parking lots, and if these facilities meet minimum size requirements, they are mapped as category 12. If they are not large enough, they are included in category 17.

Figure 6-154, a small-scale photograph, shows the layout of the Fort Leonard Wood golf course. With proper magnification, the fairways, bunkers, and greens can be identified. However, in this photograph, all that can be detected is the general cleared fairways and white spots--sand traps.

Figure 6-154.--Mapping photograph of the golf course at Fort Leonard Wood, Mo.

The fairways, darker in tone and smoother in texture than the "rough", are clearly visible on the large-scale photograph (figure 6-155). At the end of each fairway, the greens, with their associated light-toned sand traps, are easily identified. The fairways are cleared of trees or when retained, line the fairways on one or both sides.

Figure 6-155.--Large-scale photograph of Fort Leonard Wood golf course.

Site No. 18 (Cemetery)

Location: Mehlville

St. Louis County, Missouri

Geographic Coordinates: 38°30'N
90°17'W

Cemeteries are likewise included in category 17. Most larger cemeteries are within or close to an urban area. Many of the smaller rural cemeteries are too small to delineate at land use mapping scales. Cemeteries may have regular or irregular road patterns with the area generally open with shade trees bordering the roads. Figure 6-156 is a mapping photograph of the National Cemetery at Jefferson Barracks in south St. Louis County.

Figure 6-156.--Mapping photograph of National Cemetery near Mehlville, Mo.

Under magnification, figure 6-157 illustrates symmetrical patterns of the gravestones.

Figure 6-157.--Large-scale photograph of road pattern and gravestones.

Site No. 92 (Cemetery)
Location: Kirksville
Adair County, Missouri
Geographic Coordinates: 40°10'N
92°34'W

Figure 6-158 is a smaller cemetery near Kirksville, Missouri, located in the northern part of the State. The light-toned road pattern, the scattered shade trees, and lack of buildings help identify this site as a cemetery. In the vertical photograph, figure 6-158, the light-toned dot-shaped images are gravestones. Notice the linear arrangement of the graves.

The ground photograph, figure 6-159, shows the well-kept grounds and regular spacing of the grave markers.

Figure 6-158.--Large-scale photograph of the cemetery layout at Kirksville, Mo.

Figure 6-159.--Ground photograph of cemetery.

LEVEL I, CATEGORY 2 - AGRICULTURAL LAND

Agricultural Land may be defined broadly as land used primarily for production of food and fiber, or, as in the case of farmsteads, built-up service areas associated with

agricultural practices. In Missouri, approximately 63 percent of the land is used for agriculture--most of which is either cropland or pasture.

On aerial photographs, particularly high-altitude photographs, the primary recognition characteristics of agricultural activity are the distinctive geometric field and road patterns on the landscape, the traces produced by livestock or mechanized equipment, and the variations in photographic tones (gray levels) of the adjacent land parcels. Compared with the Urban or Built-up Land categories previously discussed, the number of building complexes is less and the density of the road and highway network is much lower in Agricultural Land areas. Finally, there is a marked deficiency of woodland vegetation.

The Level II categories of Agricultural Land are: Cropland and Pasture; Orchards, Groves, Vineyards, Nurseries, and Ornamental Horticultural Areas; Confined Feeding Operations; and Other Agricultural Land.

Category 21--Cropland and Pasture

Category Description. The Cropland and Pasture category includes harvested croplands, summer-fallow and idle croplands, croplands in soil-improvement grasses and legumes, croplands used for pasture in rotating crops, and improved as well as idle pasture. Approximately 62 percent (28 million acres) of Missouri is used as cropland or pasture. Of this amount, roughly two-thirds is cropland. The majority of Missouri's croplands are located in northern Missouri--north of the Missouri River. The remaining croplands are located in the bootheel area of the State and along alluvial flood plains.

It is also important to note that the U.S. Geological Survey's classification system does not separate cropland from pasture in the Level II land use and land cover mapping. Even at Level III, it is difficult to separate the two categories. Generally, a Level III differentiation between cropland and pasture areas required excessive field validation.

Concerning the separation of cropland from pasture, most croplands exist where the slopes are less than 10 percent. However, with certain conservation management practices, such as terracing, croplands may occur on slopes slightly greater than 10 percent. In the latter case, the terracing practices help to identify the areas as croplands. Accordingly, as the slope of the land increases beyond 10 percent, one finds less cropland and more pasture.

Environmental Considerations. Cropland and Pasture areas are most frequently associated with nonpoint pollution. Since the farmer must first prepare the land for planting, fertilize it, and then use pesticides to protect the crops, there are many pollution possibilities.

If tillage farming is used, loosened soil particles become prime candidates for transport to nearby water bodies. If medium to heavy precipitation follows shortly after a field has been plowed, numerous particles of soil can be transported to nearby water bodies as part of the surface runoff. The term used to refer to the condition of soil particles suspended in water is "sediment load." When a farmer does not take precautions to lessen the amount of surface soil loss which can occur with surface runoff, the number of soil particles entering nearby water bodies may increase significantly. When the sediment load becomes 1,000 parts per million or higher, there is a greater probability that aquatic plant and animal life may be adversely affected. The increase in sediment load reduces sunlight penetration, thereby reducing plant growth. Reduced plant growth reduces the level of oxygen plant production which affects the ability of certain fish species to survive in these waters.

In addition to soil erosion from plowed areas, pasture areas may also become a source for transportable soil particles, particularly where livestock overgrazing has denuded the landscape. However, the extent of soil particle contribution from overgrazing is much less than that which occurs from plowing.

In Missouri, soil loss and the subsequent increase of sediment load is by far the greatest surface water quality contaminant.

Besides the potential for increased sediment loads in nearby streams, cropland areas are also a source for such chemical pollutants as fertilizers and pesticides. As with loose soil particles, any residues from fertilizer or pesticide applications may be carried to nearby streams with surface runoff. Accordingly, the farmer must exercise care in the application of such materials to reduce the potential for water quality degradation.

Interpretation Keys. Cropland and Pasture areas are depicted in several examples which follow.

Site No. 93 (Cropland)
Location: Plymouth
Livingston County, Missouri
Geographic Coordinates: 39°37'N
93°43'W

Figure 6-160 illustrates the characteristic checkerboard pattern of cropland areas in northwestern Missouri near Plymouth. The checkerboard pattern results from different crop stages (exhibited by varying gray tones) and differences in tillage directions. Cropland areas, generally devoid of trees, possess a smoother texture than pasture land areas. A small pasture area lies just south of the east-west road to the west of a small farmstead in figure 6-160 at point A. Note the mottled texture of this area. The oblique photograph (figure 6-161) shows more clearly the characteristic checkerboard cropland pattern and the general lack of trees in cropland areas.

Figure 6-160.--Mapping photograph of cropland near Plymouth, Mo.

Figure 6-161.--Low-level photograph of cropland near Plymouth, Mo.

Site No. 44 (Pasture)
Location: Jerome
Phelps County, Missouri
Geographic Coordinates: 37°58'N
91°59'W

Figure 6-162, along the Gasconade River, presents an interesting pasture land photographic image. The white dots (or small circles) identify former locations of hay bales. Figure 6-163, of the same area but taken in winter, does not exhibit the dot pattern. Notice also the differences in gray values for the two figures. The winter scene in figure 6-163, shows the pasture area as a much lighter gray than in figure 6-162. Although the area may be in pasture at the time of figure 6-162 (June 1980), chances are that it will revert to cropland in the near future. This highlights another important point--using aerial photography, one must delineate the land use of an area according to its use at time of photographic acquisition.

Figure 6-162.--Low-level photograph of pasture land near Jerome, Mo., June 1980.

Figure 6-163.--Mapping photograph of pasture land near Jerome, January 1976.

Site No. 68 (Cropland)
Location: Chamois
Osage County, Missouri
Geographic Coordinates: 38°40'N
91°45'W

Figure 6-164 shows another cropland area near Chamois along the Missouri River. The linear pattern of cropping techniques is easily recognized and the fact that the area is devoid of trees supports classification as cropland. Figure 6-165 provides a better illustration.

Figure 6-164.--Mapping photograph of cropland near Chamois, Mo.

Figure 6-165.--Oblique photograph of cropland near Chamois, Mo.

Category 22--Orchards, Groves, Vineyards, Nurseries, and Ornamental Horticultural Areas

Category Description. Category 22 includes orchards, groves, vineyards, nurseries, and ornamental horticultural areas which produce various fruit and nut crops; nurseries and horticultural areas are used permanently for such purposes. Included in these land use categories are floricultural and seed-and-sod areas, and some greenhouses. Tree nurseries, which provide seedlings for plantation forestry, are also included in category 22 when they meet the minimum acreage requirements.

Orchards and groves are some of the more easily recognized land use types on aerial photographs, particularly during the growing season. The primary recognition feature is the grid pattern exhibited by the equally spaced rows of trees or bushes. Although the grid pattern is more easily identified on large-scale photographs, it is also discernible on high-altitude aerial photographs when they are appropriately magnified.

Environmental Considerations. Potential environment impacts from orchards, groves, and vineyards are very similar to those associated with cropland areas. Surface runoff can transport loose soil particles and various residual fertilizers, pesticides, and herbicides to nearby water bodies. To a lesser extent, nursery areas may also yield the same type of pollutants. Except for a possibility of pollution contaminants associated with the improper disposal of waste, ornamental horticultural areas are seldom a source of pollution.

Interpretation Keys. Presented below are three examples of orchards and a vineyard.

Site No. 23 (Orchard)
Location: Kelso
Scott County, Missouri
Geographic Coordinates: 37°11'N
89°33'W

Circled in figure 6-166, just south of Kelso, is an apple orchard. Because of the small scale of the photograph, one would have to view the area under magnification to clearly discern the orchard grid pattern. The orchard is seen more clearly in the oblique photograph (figure 6-167). Note the open spaces in the orchard. Apparently, the owner has lost some of the trees to disease or severe weather.

Figure 6-166.--Mapping photograph of an apple orchard south of Kelso, Mo.

Figure 6-167.--Low-level photograph of an apple orchard south of Kelso, Mo.

Site No. 41 (Orchard)
Location: Bonne Terre
St. Francois County, Missouri
Geographic Coordinates: 37°55'N
90°32'W

Another orchard is shown in figure 6-168 near Bonne Terre. This oblique photograph illustrates well the equally spaced rows common to orchards. Notice the various tones exhibited by the orchard. This is caused by growth stage differences and by differences in the crop types. The area just to the right of the pond (A) is an area of more mature apple trees. Just to the west of the pond are younger apple trees (B). The four rows just above the younger apple trees, the lighter gray area, are peach trees. The next four rows are vineyards.

Figure 6-168.--Low-level photograph of orchard at Bonne Terre, Mo.

Figure 6-169, a ground photograph of the orchard, shows three rows of apple trees to the right of the pickup (with camper), and four rows each of peach trees and grapevines.

Figure 6-169.--Orchards at Bonne Terre, Mo.

Site No. 73 (Orchard)
Location: New Franklin
Howard County, Missouri
Geographic Coordinates: 39°02'N
92°43'W

The equal spacing of orchard rows is also illustrated by this orchard near New Franklin. However, notice in this low-level photograph (figure 6-170) the gentle curved pattern of the rows. These patterns result when orchards are planted in hilly areas as opposed to the linear pattern exhibited by orchards planted on flatter terrain (see figure 6-168).

Figure 6-170.--Oblique photograph of an orchard northeast of New Franklin, Mo.

Site No. 43 (Vineyard)
Location: St. James
Phelps County, Missouri
Geographic Coordinates: 38°02'N
91°34'W

Finally, just east of St. James, large vineyards are shown in figure 6-171. It is difficult to identify vineyards on small-scale aerial photography after the frost season. Even with large-scale imagery, positive identification is difficult. The photointerpreter must be aware of the existence of vineyards in an area, and even then, must take advantage of ancillary data such as topographic maps to identify these areas.

Figure 6-171.--Oblique photograph of vineyard northeast of St. James, Mo., June 1980.

Category 23--Confined Feeding Operations

Category Description. Confined Feeding Operations are large, specialized livestock production enterprises; chiefly beef cattle feedlots, dairy operations with confined feeding, large poultry farms, and hog feedlots. Confined Feeding operations have large animal populations restricted to relatively small areas. Confined Feeding Operations exhibit a built-up appearance, chiefly composed of animal shelter buildings, fencing, access paths, and waste-disposal areas.

Environmental Considerations. Confined Feeding Operations, as noted above, tend toward large animal populations restricted to relatively small areas. If not properly maintained they can become a source for air and/or

water pollution. If animal waste is allowed to accumulate beyond acceptable levels, foul odors and various insects can become windborne. Areas downwind, such as urban residential, are subjected to high levels of air pollution.

In addition to the potential for air pollution, Confined Feeding Operations are often a source of water pollution. Since the ground surface is often denuded, periods of moderate to heavy precipitation can produce intense surface runoff which can transport such organic nutrients as phosphates and nitrates and/or loose soil particles to nearby water bodies. If the magnitude of the nutrients reaching nearby water bodies, particularly lakes or reservoirs, is significant, eutrophication can be greatly accelerated.

In some cases the trophic state of some of these water bodies is enhanced so much that they are overtaken by decaying aquatic plants to the extent that they fill up and become Nonforested Wetland areas.

In those instances where significant amounts of soil particles are transported to nearby water bodies, the increase in sediment load will often lessen the amount of sunlight penetration and thereby reduce aquatic plant production. A reduction in plant production results in a reduction in dissolved oxygen levels which may then cause these water bodies to become less suited as habitats for certain fish species.

Interpretation Keys. A cattle Confined Feeding Operation, a combination hog/cattle operation, a chicken operation, and a turkey farm are shown in the following illustrations.

Site No. 29 (Chicken Houses)
Location: Bloomfield
Stoddard County, Missouri
Geographic Coordinates: 36°53'N
89°55'W

Perhaps one of the more easily recognized types of confined feeding operations are chicken houses. Chicken houses are long, narrow wood or metal structures and most frequently occur in groups of three. Even on high-altitude photographs (figure 6-172), this characteristic pattern can be easily detected. The pattern is even more easily discerned from the oblique photograph shown in figure 6-173. Whitish tones of the chicken house roofs result from use of corrugated metal roofs which reflect a great deal of the Sun's rays.

Figure 6-174 provides a ground-level photograph of two of the three chicken houses shown in the center portion of figure 6-173.

Figure 6-172.--Mapping photograph of chicken houses east of Bloomfield, Mo.

Figure 6-173.--Low-level photograph of chicken houses east of Bloomfield, Mo.

Figure 6-174.--Chicken house east of Bloomfield, Mo.

Site No. 87 (Confined Cattle Feeding)

Location: Spickard

Grundy County, Missouri

Geographic Coordinates: 40°15'N
93°13'W

Another type of confined feeding which is easily recognized is that of confined cattle feeding. Circled in figure 6-175 is a confined cattle feeding operation at Spickard, Missouri. Lack of vegetation is shown clearly on the vertical photograph of figure 6-176. Note the whitish areas near the animal shelter buildings. These areas are devoid of vegetation. Also notice the rectangular shape of the fenced feedlots. Just to the northwest of the larger animal shelter buildings are a series of smaller buildings and narrower feedlots. The feedlots at A are not presently in use. Examination of the smaller feedlots reveals that a distinct texture difference exists. The smooth-textured area lots are used more frequently. The less frequently used lots (A) have grown up with vegetation and therefore, exhibit a coarser texture.

Figure 6-175.--Mapping photograph of confined cattle feeding near Spickard, Mo.

Figure 6-176.--Low-level photograph of confined cattle feeding operation near Spickard, Mo.

Site No. 86 (Confined Hog and Cattle Feeding)

Location: Ravenwood

Nodaway County, Missouri

Geographic Coordinates: 40°25'N
94°40'W

Another example of confined feeding is illustrated in the oblique and vertical photographs shown in figures 6-177 and 6-178. Two types of confined feeding operations are apparent. In figure 6-178, eight rather large rectangular feedlots are shown in the middle of the photograph. They are very similar in appearance to the feedlots shown earlier in figure 6-176; therefore, one would expect to find cattle here. However, when the imagery was enlarged, it appeared as though the eastern feedlots were also being used for hogs. To the west of these feedlots, just north of a small pond, are located 12 smaller hog feedlots. The whitish area leading away from the feedlots to the pond is used during cleanup operations. The pond serves as a settling pond.

The differences in tone and texture can be used to identify the various stages of use for the larger feedlots. The fourth feedlot from the north at A in figure 6-178, as shown by its courser texture and spotted tone, has not been used recently. However, note that the second feedlot from the north has a smoother texture and more even gray tones. Under appropriate magnification, more than a dozen hogs are visible in the second feedlot. Another item commonly associated with confined feeding operations, in addition to the animal shelter buildings, are feed storage tanks. Located at the extreme top of figure 6-178, at B, can be seen five feed storage tanks.

Figure 6-177.--Low-level oblique photograph of confined feeding operation north of Ravenwood.

Figure 6-178.--Low-level vertical photograph of confined feeding operation north of Ravenwood.

Site No. 95 (Turkey Farm)
 Location: Winigan
 Sullivan County, Missouri
 Geographic Coordinates: 40°02'N
 92°56'W

Also included in land use category 23 are turkey farms. Turkey farms are rather difficult to identify on high-altitude aerial photographs. Therefore, prior knowledge of their existence in an area is normally required to increase the probability of correct photographic identification. Four turkey farm areas are shown in the oblique photograph of figure 6-179. The turkey farms are located just west of Winigan, Missouri. Two of the areas are active (A and B), two are inactive (C and D). The inactive areas appear whitish in tone with small, darker squares indicating the former locations of portable range shelters now located at A and B.

Although open range feeding of turkeys is an identification feature of this category, the areas in which the birds feed would not be delineated as confined feeding. The brooder houses themselves and auxillary structures would be the only area to be delineated.

Figure 6-179.--Low-level oblique photograph of a turkey farm near Winigan, Mo.

The vertical photograph of figure 6-180 clearly illustrates the practice of relocating turkey farm areas once an area has been denuded of vegetation. Note the small darker gray rectangular spots paralleling the road (A). These spots mark the former positions of the range shelters. The range shelters, as well as most of the turkey feeders, have been moved to a new position just to the south of their old location (B). The range shelters, without sides, are constructed to allow the turkeys to get out of the sun during the hot summer months. During winter, the turkeys are housed in large, long poultry houses such as those seen in the ground-level photograph of figure 6-181 just east of the area shown in figure 6-180.

Figure 6-180.--Low-level photograph of turkey farm area near Winigan, Mo.

Figure 6-181.--Turkey brooder house near Winigan, Mo.

Category 24--Other Agricultural Land

Category Description. The Other
Agricultural Land category includes farmsteads, holding areas for livestock such as corrals, farm lanes and roads, ditches and canals, small farm ponds, fish farms and hatcheries, horse farms, and other similar associated built-up features adjacent to and closely associated with agricultural resource management.

Environmental Considerations. The pollution potential from Other Agricultural Land areas is very similar to the other Level II categories of Agricultural land previously discussed; that is, Other Agricultural Land areas may become sources for nonpoint water pollution. However, primarily because of their relatively small areal extent, the pollution potential from these areas is less than that from the more extensive Agricultural Land Level II categories.

Also included in the Other Agricultural Land category are fish hatchery operations. After a period of time, fish hatchery ponds may become saturated with waste (such as phosphates and nitrates) and various disease organisms. If there is a discharge of fish pond waters due to flooding, breaching, leaching, or a deliberate release, several conditions may ensue: eutrophication of nearby water bodies may occur; disease organisms may spread; or the escape of non-native fish species into nearby water bodies may lead to the depletion of natural stocks by predation or competitive exclusion.

Fish hatchery operations may also generate foul odors, particularly from a fish kill which will attract insects and cause diseases

to spread. Abandoned fish ponds, left filled with water, are also possible insect breeding areas.

Interpretation Keys. The Other
Agricultural Land category is illustrated by a fish farm and farmstead.

Site No. 38 (Fish Farm)

Location: Montreal

Camden County, Missouri

Geographic Coordinates: 37°53'N
92°31'W

Fish farms are shallow manmade water bodies maintained for the purpose of raising fish for wholesale trade. Quite often, due to differences in water depths or sediment loads and algae concentrations, the adjoining irregularly shaped water bodies exhibit a variety of shades from gray to black. Figure 6-182 illustrates this well. The differences in the shades of gray are illustrated even more clearly in the oblique photograph (figure 6-183) of the southernmost fish farm ponds shown in figure 6-182. A ground-level photograph (figure 6-184) further illustrates the shape of the individual fish farm ponds and provides the reader with an appreciation for the widths of the holding levees separating the ponds. The levees provide the owners access to the ponds for maintenance and harvesting.

Figure 6-182.--Mapping photograph of a fish farm southeast of Montreal, Mo.

Most fish farms will be found in stream valleys. The stream water will flow directly through or be directed into the ponding areas. In southeast Missouri in rice production areas, reservoirs used to store water for the fields are used part of the year for fish production. These types of fish ponds are impossible to delineate without ground observation.

Figure 6-183.--Low-level photograph of fish farm ponds southeast of Montreal, Mo.

Figure 6-184.--Fish farm ponds near Montreal, Mo.

Site No. 99 (Farmstead)
 Location: Maitland
 Holt County, Missouri
 Geographic Coordinates: 40°07'N
 95°04'W

Farmsteads are built-up service areas associated with agricultural practices. In order for farmsteads to be shown on a land use map, they must meet the minimum mapping size requirements for the scale of the map. On land use maps at a publication scale of 1:250,000, farmsteads must be at least 10 acres in size to be shown. Circled in figure 6-185 is a farmstead approximately 6 miles south of Maitland, Missouri. The built-up photographic signature of the farmstead, surrounded by cropland and pasture, is easily identified. The oblique photograph (figure 6-186) further illustrates the extent of the built-up features associated with this farmstead. Noted on the photograph are residential structures at A, B, and C; feed storage tanks at D; tractors at E; and several rectangular shelter/storage buildings at F. In addition to the built-up signature displayed by the farmstead, the lighter gray tone of the farmstead draws the attention to the site.

Figure 6-185.--Mapping photograph of a farmstead south of Maitland, Mo.

Figure 6-186.--Low-level oblique photograph of the farmstead near Maitland, Mo.

LEVEL I, CATEGORY 3 - RANGELAND

Historically, Rangeland has been defined as land on which the potential natural vegetation is predominately grasses, grasslike plants, forbs, or shrubs and where natural herbivory was an important influence in its precivilization state. Generally, management practices do not include fertilization, cultivation, or irrigation. Instead, Rangeland management practices follow ecological principles of resource management.

In Missouri, what little Herbaceous Rangeland there is, primarily is located in the west-central and southwest portions of the State. Shrub and Brush Rangeland, specifically eastern brushland vegetation, is found in the same areas as Cropland and Pasture; namely, north of the Missouri River and along the Mississippi River floodplain.

Category 31--Herbaceous Rangeland

Category Description. Herbaceous Rangeland encompasses lands dominated by naturally occurring grasses and forbs as well as those areas of natural rangeland which have been modified to include grasses and forbs as their principal cover, when managed for rangeland purposes and not managed using typical pastureland practices.

As noted earlier, the Herbaceous Rangeland areas of Missouri occur in the west-central and southwestern portions of the State. Unlike the more expansive Herbaceous Rangeland areas found from the Texas Panhandle northward to the Dakotas, Missouri Herbaceous Rangeland areas are boxed in by Cropland and Pasture; Therefore, it is difficult to accurately identify Herbaceous Rangeland areas on high-altitude photographs. The boxed-in shape of these areas robs the photointerpreter of one of the most important photorecognition characteristics of the more expansive Herbaceous Rangeland areas--the irregularly shaped natural landscape. Not only are there so few areas of Herbaceous Rangeland in Missouri, but add to this the fact that these areas are difficult to identify on high-altitude aerial photographs, and it can be realized why there is a high potential for an understatement of the total Herbaceous Rangeland acres in the State.

Environmental Considerations. Herbaceous Rangeland areas are, by definition, areas which are managed by ecological resource management principles rather than by fertilizing, cultivating, or irrigation. Therefore, such areas are not a potential pollution source.

Interpretation Keys. Since Herbaceous Rangeland areas are of limited extent in Missouri, there are few good examples of this land use category. However, the forb prairie just west of Kingdom City, Missouri, provides an excellent example.

Site No. 102 (Forb Prairie)

Location: Kingdom City

Callaway County, Missouri

Geographic Coordinates: 39°57'N

92°00'W

Most of the Herbaceous Rangeland that exists in Missouri is owned and/or protected by the Missouri Department of Conservation. As of 1978, the State had 23 public prairies totaling over 6,000 acres. These prairies were owned by either the Missouri Department of Conservation, the Missouri Prairie Foundation, the Nature Conservancy, the University of Missouri, or a combination of the above. One of these sites, Tucker Prairie, is circled in figure 6-187. Under appropriate magnification, one can discern a difference in the Cropland fields surrounding the prairie and the prairie itself. The Cropland fields retain signs of tillage, while the prairie areas do not. Had the surrounding areas been Pasture rather than Cropland, it would have been more difficult to identify prairie areas.

Even the use of low-level imagery adds little to assisting the photointerpreter in identifying the area as Herbaceous Rangeland (see figure 6-188). Only when verified by ground observations can one be confident of an accurate classification of Herbaceous Rangeland in Missouri (see figure 6-189). This photograph illustrates a field of black-eyed Susans, a typical forb vegetation.

Figure 6-187.--Mapping photograph of forb prairie west of Kingdom City, Mo.

Figure 6-188.--Oblique photograph of forb prairie west of Kingdom City, Mo.

Figure 6-189.--Tucker (forb) Prairie west of Kingdom City--ground observation.

Category 32--Shrub and Brush Rangeland

Category Description. Shrub or scrub vegetation, characteristic of arid or semiarid regions, is not found in Missouri. Eastern brushland areas, however, do occur primarily north of the Missouri River and adjacent to the Mississippi River north of Cape Girardeau.

Eastern brushlands are typically former croplands or pasture lands (cleared from original forest lands) which are being allowed to revert to their natural state. Accordingly, these areas, grown up in brush, are in transition back to forest land to the extent that they are no longer identifiable as cropland or pasture. Many of these areas are extensively grazed by livestock and provide wildlife

habitat. More often, they are retained as part of the farm, but are not used at their former levels of intensity. Traditionally, botanists have not included eastern brushland areas in the Rangeland category because of their original forested state prior to clearing for cropland or pasture; therefore, they have been summarized statistically with pasture land. However, since they primarily function as grazing land, they are included in the U.S. Geological Survey's classification system's Rangeland category. Following sufficient reforestation, these areas should be classified as Forest Land.

Environmental Considerations. Eastern brushland areas, particularly in their early stages of development, may reduce water quality as surface runoff transports loose soil particles to nearby water bodies. However, as these areas mature and are retained in Rangeland, there are few, if any, contaminant sources associated with eastern brushland areas.

Interpretation Keys. Examples of eastern brushland can be found in many areas of the State. The following example, near New Hampton, is illustrative of this land use category.

Site No. 84 (Eastern Brushland)

Location: New Hampton

Harrison County, Missouri

Geographic Coordinates: 40°16'N

94°10'W

Circled in figure 6-190, just east of New Hampton, is an example of eastern brushland as it appears on mapping photographs. Notice the slightly darker gray tone and coarser texture exhibited by the presence of the brushland

Figure 6-190.--Mapping photograph of eastern brushland area near New Hampton, Mo.

vegetation. Vegetation nearest the railroad (the southern boundary of the area) is actually too dense to be classified as eastern brushland. However, because the strip does not meet minimum mapping width criteria at the 1:250,000 scale, this more heavily vegetated strip should be combined with the eastern brushland to the north and shown as eastern brushland.

Figure 6-191 illustrates more clearly the characteristic vegetation pattern of eastern brushland. Notice the denser strip of trees near the bottom of the photograph.

Figure 6-191.--Oblique photograph of eastern brushland area near New Hampton, Mo.

LEVEL I, CATEGORY 4 - FOREST LAND

Areas of trees capable of producing timber and other wood products, which exhibit a tree-crown areal density (crown closure percentage) of 10 percent or more, and exert an influence on the climate or water regime, are classified as Forest Land. Although the precise boundary between Forest Land and other categories of land use may be difficult to delineate, generally Forest Land areas can be identified rather easily on high-altitude aerial photographs. The majority of the Forest Land in Missouri is located south of a line extending from Joplin in the southwest through Columbia to Hannibal in the northeast. Statewide, over 15 million acres of Forest Land cover Missouri.

Also included in the Forest Land category are lands from which trees have been removed to less than 10 percent crown closure but which have not been developed for other uses. These areas often have been clear cut and are scheduled for blockplanting. This practice is commonplace in our national forest lands.

Not included in the Forest Land category are those areas which would otherwise be

classified as Forest land if it were not for the fact that the water table was at or near the ground surface. Since the wetland condition is of much interest to land managers and planning groups, such lands are classified as Forested Wetland.

At Level II, Forest Land is separated into three categories: Deciduous, Evergreen, and Mixed. From small-scale aerial photographs, the photointerpreter must rely on site association knowledge, tone, and texture analysis to differentiate these cover categories. In addition, the availability of photographs obtained during the period when deciduous trees are bare can be very helpful in separating Deciduous and Evergreen Forest cover types.

Prior to initiating Forest Land photointerpretation, the photointerpreter should be familiar with the various tree species known to exist in the area. This task can be facilitated by consulting silviculture handbooks normally available from State or Federal service agencies for the area.

Photographic tone can also be used to help identify forest cover types. Generally, evergreen trees exhibit a darker tone (dark green) than deciduous trees. On color-infrared winter photographs, evergreen trees are generally magenta in color.

Concerning photographic texture, even-aged coniferous trees generally exhibit a smooth, carpetlike texture. Deciduous trees, on the other hand, exhibit a rougher texture as a result of their varying heights and rounded crowns, particularly when the stands are of an uneven-aged nature.

Category 41--Deciduous Forest Land

Category Description. Deciduous Forest Lands include all forested areas with a predominance of trees that lose their leaves at the end of the frost-free season or at the beginning of the dry season. Nearly 94 percent of Missouri's 15 million acres of Forest Land is of the deciduous cover type--mostly oak.

The geographic extent of the Deciduous Forest Land parallels that of Missouri's Forest Land; that is, the majority of the Deciduous Forest Land occurs south of a line extending from Joplin to Columbia to Hannibal.

Environmental Considerations. Deciduous Forest Land areas exert a strong influence on local water supplies and microclimatic conditions. Silvicultural management practices may effect both the quantity and quality of nearby water bodies. Since the types of pollution which may occur from Deciduous Forest Lands

would be the same for Evergreen Forest Lands and Mixed Forest Lands, a detailed description of environmental considerations is presented only for the Deciduous Forest Land category rather than each Level II Forest Land category.

Thinning and harvesting operations may increase water quantity by reducing existing transpirational surface areas and decrease water quality as a consequence of the transport of chemical (primarily herbicides, insecticides, and fertilizers) and physical (loose soil particles) contaminants to nearby water bodies with surface runoff.

The use of herbicides for plantation clearing, site preparation, right-of-way maintenance, and other uses may contaminate the soil, wildlife, and surface or ground-water supplies. Insecticides, used to check the spread of harmful pests, can cause both air and water pollution--not to mention the possibility of adversely affecting certain beneficial species such as honey bees.

Forest fertilization, if improperly administered, can increase the nutrient load of nearby water bodies and thereby increase existing trophic states. Logging road construction and maintenance activities can lead to erosion and increase nearby water course sediment loads. Repeated passes of logging equipment over the area can result in soil compaction, reduce percolation rates, and as a consequence, intensify surface runoff rates--even to the extent that it may cause minor flooding and the loss of tree vigor.

Interpretation Keys. The Deciduous Forest Land areas at Windsor (west-central Missouri) and Kirksville (northeast Missouri) illustrate land use category 41.

Site No. 74 (Reforested Strip Mine)
Location: Windsor
Henry County, Missouri
Geographic Coordinates: 38°34'N
93°35'W

A number of areas in the State which have been strip mined have been allowed to return to Forest Land vegetation. One such area, approximately 6 miles west of Windsor, is circled in figure 6-192. Notice the alternating rows of white (ridges) and dark (forested troughs) in the upper left portion of the circle. Figure 6-193, an oblique photograph of the same area, reveals the extent to which additional deciduous tree growth has occurred between 1972 and 1980. Just to the southwest of the strip mines shown in figure 6-192 is an excellent example of a larger strip mined area

Figure 6-192.--Mapping photograph of strip mine area west of Windsor, Mo., undergoing natural reforestation, 1972.

Figure 6-193.--Low-level oblique photograph of reforested strip mine area, 1980.

Figure 6-194.--Low-level vertical photograph of mature, natural reforestation of former strip mine area southwest of Windsor.

after more than 30 years of natural reforestation. Notice the two types of forest cover shown in figure 6-194. The smoother textured, area, circled, is an area of coniferous forest cover. The remaining area is covered by deciduous trees.

Site No. 94 (Deciduous Trees)
Location: Kirksville
Adair County, Missouri
Geographic Coordinates: 40°11'N
92°38'W

Another example of Deciduous Forest is shown in figure 6-195. This site, at Thousand Hills State Park just west of Kirksville, Missouri, also provides an excellent example of coniferous evergreen trees adjacent to deciduous trees. Although coniferous trees are not native to the area, Boy Scouts voluntarily planted some scotch pines in several places in the park about 25 years ago. The coniferous trees stand out as the darker tone areas in figure 6-195.

Figure 6-196, an oblique photograph taken 6 years later, shows an area of defoliated trees at A. A recent forest fire has destroyed some of the scotch pines. To the east of the defoliated area are the deciduous trees with their characteristic, more rounded tree crowns (B). Notice that the deciduous trees generally have a lighter tone on black-and-white photographs. Had frost-season photography been available, it would have also been helpful in separating the deciduous from the evergreen trees.

Figure 6-195.--Mapping photograph of deciduous and evergreen forest cover in Thousand Hills State Park, 1974.

Figure 6-196.--Low-level 1980 oblique photograph of a portion of the area shown in figure 6-195.

Category 42--Evergreen Forest Land

Category Description. Forest areas in which the trees are predominately those which remain green throughout the year are classified as Evergreen Forest Lands. Included in this category are both coniferous and broadleaved evergreens. Evergreen species commonly associated with Wetland areas are not included in this category.

The two most common species of evergreens occurring in Missouri are the shortleaf pine (*pinus echinata*) and the eastern redcedar (*juniperus virginiana*). The former is found primarily in the southeastern part of the State while the latter can be found in extreme east-central Missouri and in some east-central counties.

Environmental Considerations. The environmental description presented earlier for land use category 41, Deciduous Forest Land, applies to Evergreen Forest Land areas as well; therefore, refer to land use category 41 for information on the potential pollution contaminants most likely to be associated with Evergreen Forest Land.

Interpretation Keys. Presented below are examples of planted pine at New Madrid and eastern redcedar near Bradleyville (south-central Missouri).

Site No. 25 (Plantation Pine)
 Location: New Madrid
 New Madrid County, Missouri
 Geographic Coordinates: 36°32'N
 89°26'W

Located about 3 miles southeast of New Madrid is a rectangular area of planted short-leaf pine. Photographed in 1974, notice the height differences between the planted pine and the adjacent deciduous trees in figure 6-197. Figure 6-198, an oblique photograph of the same area in 1980, illustrates both the rapid rate of tree growth exhibited by this species in southeast Missouri and the characteristic carpetlike texture common to even-aged coniferous tree cover. Although not the case with this particular pine plantation, many pine plantations are actually planted in rows. When viewed from the air, or on an aerial photographs, row pine plantations are easily identified.

Figure 6-197.--Mapping photograph of planted pine near New Madrid, Mo., 1974.

Figure 6-198.--Low-level oblique photograph of planted pine near New Madrid, 1980.

Site No. 65 (Eastern Redcedar)
 Location: Bradleyville
 Taney County, Missouri
 Geographic Coordinates: 36°46'N
 92°57'W

The second most prevalent type of Evergreen Forest Land, eastern redcedar, is shown in figure 6-199 at A. This area barely meets the minimum mapping size of 40 acres required for 1:250,000-scale land use and land cover mapping. The photograph, taken on January 23, 1976, allows the photointerpreter to easily separate deciduous and evergreen trees. The darker tone areas are eastern redcedars (evergreens) while the lighter tone areas, particularly on the right side of figure 6-199 at B, are deciduous trees which have lost their leaves. In the upper-left portion of figure 6-199 is an area of Mixed Forest Land; that is, an area of evergreen and deciduous trees where neither predominates. Figure 6-200, an oblique photograph, illustrates the darker tone of the cedar trees. Notice how the cedar trees parallel the limestone bedding plains as they curve around the hillsides. The areas devoid of tree cover have been cleared for pasture. A comparison between figure 6-199 and figure 6-200 reveals the extent of additional clearing that occurred at A between 1976 and 1980.

Figure 6-199.--Mapping photograph of eastern redcedar forest cover southwest of Bradleyville, January 1976.

Figure 6-200.--Low-level oblique photograph of eastern redcedar forest cover near Bradleyville, July 1980.

Category 43--Mixed Forest Land

Category Description. A Forest Land area is classified as Mixed Forest when more than one-third intermixture of either evergreen or deciduous tree species occurs in a specific area. In actuality, this division of the Forest Land category is a function of the land use and land cover mapping specifications and, therefore, will be less often used at some mapping scales than others, particularly at larger mapping scales.

Environmental Considerations. The environmental description presented earlier for land use category 41, Deciduous Forest Land, applies to Mixed Forest Land areas as well; therefore refer to land use category 41 for information on the potential pollution contaminants most likely to be associated with Mixed Forest Land.

Interpretation Keys. Site 39, near Edgehill, presents an example of Mixed Forest Land.

Site No. 39 (Mixed Deciduous and
Evergreen Forest Cover)
Location: Edgehill
Iron County, Missouri
Geographic Coordinates: 37°37'N
90°54'W

An example of Mixed Forest Land is illustrated by figure 6-201. This area, approximately 3 miles north-northeast of Edgehill, has varying degrees of deciduous (lighter tone areas) and evergreen (darker tone areas) trees. Notice the small, but more homogeneous, stands of darker tone evergreen trees (circled on the photograph) surrounded by deciduous trees. Because this photograph was taken during the frost season (photo date March 9, 1980), the deciduous trees exhibit an even lighter tone than had the photo been taken during the frost-free season. Quite often, frost season (leaf-off) photographs are not available. In such cases, if color-infrared photographs are available, the task of separating deciduous and evergreen trees or delineating Mixed Forest Land areas is facilitated. Figure 6-202, a black-and-white reproduction of a high-altitude color-infrared (CIR) photograph taken in September 1974, illustrates the benefits to be gained from the use of CIR photographs--even when they are reproduced in black-and-white. The evergreen trees appear as darker tones on the photograph. Notice the dark tone of the purer stands of evergreen trees at A. The deciduous trees are lighter in tone. Also notice, particularly along stream segments, the lighter tone of the deciduous trees which have begun to lose their leaves. In such cases these linear areas appear whitish to gray in tone. The lighter, almost white, areas in the photograph are rock outcroppings.

Figure 6-201.--Black-and-white reproduction of a mapping photograph of mixed forest cover near Edgehill, March 1980.

Figure 6-202.--Black-and-white reproduction of a color-infrared mapping photograph of mixed forest cover near Edgehill, September 1974.

LEVEL I, CATEGORY 5--WATER

Water areas, as defined by the Bureau of the Census, include all areas within the land mass of the United States that are persistently covered by water, at least 40 acres in size, and if linear, are at least 1/8 mile wide. However, for most purposes, agencies require the identification of water bodies smaller than 40 acres. The U.S. Geological Survey land use and land cover maps include all water bodies greater than 10 acres which are at least 300 feet wide and shown as double-line streams on the 1:250,000-scale base map. Water included in this category are streams and canals, lakes, reservoirs, and bays and estuaries.

At the 1:250,000-scale land use and land cover mapping for Missouri, only major rivers, such as the Mississippi, Missouri, and Osage, and major canals, such as those near Kennett in southeast Missouri, are shown. Natural lakes are rare with less than 17 square miles of this land use type in the State. More common are the State's many reservoirs. Reservoirs such as Clearwater, Pomme de Terre, Stockton, and Table Rock account for over 232,000 acres of State's reservoirs. Bays and estuaries are not found in Missouri.

The above acreage figures reflect water area totals based on Level II land use and land cover mapping at the 1:250,000 scale. At a larger mapping scale and a greater level of land use detail, these acreage totals increase somewhat.

It is important to note that all water bodies should be delineated as they exist at the date (time) of the photography, except areas in an obvious state of flood.

Category 51--Streams and Canals

Category Description. Included in the Streams and Canals category are rivers, creeks, canals, and other linear water bodies. Where the water course is interrupted by a control structure, the impounded area is placed in the Reservoir category.

Environmental Considerations. Streams and canals are not in themselves pollution sources. Instead, it is the discharge from point sources and surface runoff from nonpoint pollution sources, such as agricultural and silvicultural areas, which reduce stream and canal water quality. Perhaps flooding is the most serious detrimental effect which can occur from streams. When streams overflow their banks they can, and have, caused significant damage to manmade structures and crops.

Interpretation Keys. Two sites, site 70 and 26, follow which depict rivers and canals.

Site No. 70 (Missouri River)
Location: Jefferson City
Cole County, Missouri
Geographic Coordinates: 38°35'N
92°11'W

Rivers and streams are easily recognized on aerial photographs. As shown in figure 6-203, natural water courses consist of somewhat parallel land/water interface boundaries which quite often vary in width as a function of normal fluvial processes. Water bodies are most often characterized by medium gray tones on aerial photographs. Figure 6-204 is an oblique photograph of the same section of the Missouri River at Jefferson City. Notice the bridge over the river and the barges docked on the northern shore.

Figure 6-203.--Mapping photograph of Missouri River at Jefferson City, Mo.

Figure 6-204.--Oblique photograph of Missouri River at Jefferson City, Mo.

Site No. 26 (Canals)

Location: Kennett

Dunklin County, Missouri

Geographic Coordinates: 36°10'N

90°01'W

Canals, or ditches, are constructed for one of two purposes: to drain or to irrigate an area. Around the turn of the century, a number of drainage ditches were constructed in southeast Missouri extending from south of Cape Girardeau to across the Missouri/Arkansas State line. This area, once swampy and marshy, is now very productive cropland. From a weblike network of ditches north of Gideon, many of the smaller ditches finally enter one of five main ditches about 3 miles southeast of Gideon where the five ditches extend southwest for almost 35 miles. Pictured in figure 6-205 is a segment of the five main drainage ditches about 4.5 miles southeast of Kennett. Unlike natural linear water courses (streams and rivers), canals and ditches have parallel land/water interface boundaries of nearly constant separation. Three of the ditches in the photograph appear medium gray in tone--the two westernmost ditches and the easternmost one. The two other ditches are lighter gray, almost white. The difference in tone can be explained by slight differences in water levels, camera angles, and subsequent Sun reflections. The lighter gray tone ditches are reflecting more sunlight and therefore show up as light gray in the photograph.

Figure 6-206, an oblique photograph of the same area, also shows differences in gray tone values for the ditches; however, in this case, only one ditch reflects more sunlight.

Figure 6-205.--Mapping photograph of canals near Kennett, Mo.

Figure 6-206.--Oblique photograph of canals near Kennett, Mo.

Figure 6-207.--Ground shot of drainage canal near Kennett, Mo.

Figure 6-207 is a ground-level photograph of one of the ditches taken from a bridge 6 miles northwest of the location shown in figures 6-205 and 6-206. Notice how straight the water course is and its constant width.

Category 52--Lakes

Category Description. Lakes are naturally enclosed standing water bodies, including regulated natural lakes but excluding reservoirs. Only lakes 10 acres or greater at the time of photoacquisition are delineated on the U.S. Geological Survey 1:250,000-scale land use and land cover maps. If the photointerpreter has source material which provides the name of a water body, he should not necessarily classify the water body from this information because many reservoirs in Missouri have lake names. Accordingly, the majority of Missouri's nonlinear water bodies are reservoirs and not lakes. It is important to remember that lake water levels are maintained by the seepage of ground water and the direct surface runoff of precipitation, whereas reservoir water levels are the result of manmade impoundments and the subsequent accumulation of surface runoff, primarily by contributing linear water courses.

For the most part, Missouri lakes are found in the flood plains of the State's two largest rivers--the Mississippi and the Missouri. These lakes, called oxbow lakes, are formed by sealing off the meanders of alluvial streams. As alluvial streams mature, their meanders (snake-like patterns) grow until the channels bend to meet themselves, causing the meander loops to be pinched (sealed) off and abandoned--therefore, oxbow lakes can be found all along the Missouri and Mississippi Rivers.

Environmental Considerations. Like streams and canals, lakes are not in themselves pollution sources. The same types of point and nonpoint pollution sources which affect linear water bodies also affect lakes. However, unlike linear water bodies, lakes do not possess the same flood hazard potential. Therefore, one is more likely to find manmade construction, namely houses and businesses, closer to the land/water interface boundaries of lakes than streams or rivers.

Interpretation Keys. Site 83, an oxbow lake west of Fortescue, Missouri, characterizes Missouri lakes.

Site No. 83 (Oxbow Lake)

Location: Fortescue

Holt County, Missouri

Geographic Coordinates: 40°05'N
95°21'W

Located west of Fortescue, Big Lake is one of Missouri's many oxbow lakes. In figure 6-208, it appears as a crescent shape with the crescent ends pointing west toward the Missouri River. Close inspection of the photograph reveals a series of meander scars to the east. Figure 6-209, an oblique photograph of the northern half of the lake, shows the extent to which resort-type residential structures rim the land/water interface boundary.

Figure 6-208.--Mapping photograph of an oxbow lake west of Fortescue, Mo.

Figure 6-209.--Oblique photograph of a portion of Big Lake west of Fortescue.

Category 53--Reservoirs

Category Description. Manmade impoundments of water used for such purposes as irrigation, flood control, municipal water supplies, recreation, and hydroelectric power generation are classified as reservoirs. On aerial photographs, reservoirs are identified by their overall nonlinear shape and associated manmade water-control structures--such as dams or levees. It is the manmade water-control structures which key the photointerpreter to classify a nonlinear water body as a reservoir. As with land use category 52 (Lakes), only reservoirs 10 acres or greater at the time of photoacquisition are delineated on 1:250,000-scale land use and land cover maps. Accordingly, many farm ponds in Missouri are not included in the acreage figures for reservoirs presented in Section 7. Of the State's 377,022 acres of water, 232,559 acres (61 percent) are represented by the Reservoir category. This category includes reservoirs such as Table Rock Lake, Stockton Lake, Lake of the Ozarks, Clearwater Lake, Clarence Cannon Lake, and many more smaller reservoirs around the State.

Environmental Considerations. Comments previously presented as environmental considerations for lakes hold true for reservoirs. Concerning flood hazard potential, the most dreaded occurrence would be a dam break. Fortunately however, such occurrences are rare.

Interpretation Keys. The Clearwater Lake Reservoir exemplifies many Missouri reservoirs.

Site No. 33 (Clearwater Lake Reservoir)

Location: Piedmont

Wayne County, Missouri

Geographic Coordinates: 37°08'N
90°46'W

Located approximately 4 miles west of Piedmont, Clearwater Lake Reservoir is one of Missouri's excellent recreational areas. Around the reservoir's perimeter are a number of public access points and use areas. Some of these areas are identified in figure 6-210 at A, B, and C; also shown is the dam at D. Note the straight land/water interface formed by the dam and the water.

Figure 6-211 shows more clearly the back side of the dam and some of the recreational/camping facilities. In figure 6-212, several campers and trailers can be seen parked at the site. Also shown in figure 6-211, at A, is a boat ramp. Figure 6-213 shows a ground photograph of the boat ramp area.

Figure 6-210.--Mapping photograph of Clearwater Lake Reservoir near Piedmont, Mo.

Figure 6-211.--Oblique photograph of Clearwater Dam near Piedmont, Mo.

Figure 6-212.--Camping area at Clearwater Dam near Piedmont, Mo.

Figure 6-213.--Public use area and boat ramp at Clearwater Lake Reservoir near Piedmont, Mo.

LEVEL I, CATEGORY 6--WETLAND

Wetland areas are areas where the water table is at, near, or above the land surface for a significant part of most years. The hydrologic regime is such that aquatic or hydrophytic vegetation is established, however, alluvial and tidal flats may be nonvegetated. Examples of wetlands include swamps, marshes, mudflats, and portions of streams, lakes, reservoirs, and bays which exhibit surface aquatic or hydrophytic vegetation. Shallow water areas where aquatic vegetation is submerged are classified as open water and not included in the Wetland category.

Extensive parts of some river flood plains qualify as Wetland, as do regularly

flooded irrigation overflow areas. Not included in the Wetland category are agricultural lands where seasonal wetness or short-term flooding provides an important component of the total annual soil moisture necessary for crop production; for example, flooded fields associated with rice production or developed cranberry bogs.

Uncultivated Wetland, from which wild rice, cattails, or wood products, and other crops are harvested, or Wetland grazed by livestock, are placed in the Wetland category.

Wetland areas drained for any purpose belong to the land use and land cover category for which they are being used. If, however, drainage is discontinued and such use ceases, classification may revert to the Wetland category. Wetland managed for wildlife purposes may exhibit short-term land use changes as different management practices are used; however, such areas should be classified as Wetland.

With regard to the delineation of Wetland areas, two separate boundaries are important: the upper wetland boundary above which almost any non-wetland category of land use or land cover may exist, and the boundary between wetland and open water beyond which the appropriate Water category should be utilized.

Wetland areas in Missouri occur primarily along the Mississippi and Missouri River flood plains, the upper reaches of reservoirs, and in the Missouri bootheel counties of Wayne, Stoddard, Bollinger, Mississippi, and Dunklin. These five counties account for slightly more than one-third of all of Missouri's 66,862 acres of Wetland.

The Level II categories of Wetland are Forested Wetland and Nonforested Wetland. Approximately two-thirds (46,585 acres) of Missouri's Wetland areas are Forested Wetland.

Category 61--Forested Wetland

Category Description. Wetlands dominated by woody vegetation are classified as Forested Wetland. In Missouri, the Forested Wetland category is primarily represented by bottomland oaks such as pine; swamp, white, and shingle oaks; and tupelo, blackgum, sweetgum, and cypress species.

Extensive Forested Wetland areas are usually more easily identified on color-infrared (CIR) photography than on color or black-and-white photography. These areas exhibit a bluish cast on CIR imagery as opposed to the red colors of deciduous trees and magenta colors of the evergreens.

If available, ground surveys of soil types or the duration of flooding can provide supplemental information to assist the photointerpreter in delineating Forested Wetland areas. Many times photographs acquired with low Sun angles will aid in detecting standing water areas where tree crown closure values are not too great.

Environmental Considerations. Like water, Forested Wetland areas do not cause pollution. These areas, however, can become victims of a range of man's activities which can ruin an otherwise balanced ecosystem. In Missouri, the greatest potential pollution source for Forested Wetland areas is nonpoint pollution, primarily runoff from adjacent agricultural areas. If proper precautions are not taken, agricultural areas may introduce such pollutants as livestock manure, fertilizers, and pesticides.

Interpretation Keys. Two sites, both in southeast Missouri, are described below to illustrate Forested Wetland areas.

Site No. 31 (Swamp)
Location: Puxico
Stoddard County, Missouri
Geographic Coordinates: 37°01'N
90°10'W

Figure 6-214, a black-and-white reproduction of a color-infrared photograph of a portion of the Mingo National Wildlife Refuge (approximately 3 miles north of Puxico), depicts both land use categories 61 (Forested Wetland), at A, and 62 (Nonforested Wetland), at B. Notice the dark areas as opposed to the lighter area just above A. The dark areas are wetter areas of woody vegetation, while the lighter areas are higher, drier areas of forest land. The lighter area at B, Nonforested Wetland, is discussed later.

On color-infrared photography, the Forested Wetland areas appear bluish in color while the drier deciduous forest areas appear red in summer. During the frost season, deciduous trees appear as blue-green when the leaves are brown, yellow when the leaves are red, and white when the leaves are yellow. The photograph shown in figure 6-214 was taken in November 1974, when the leaves had already turned brown; therefore, on the color-infrared photography, the trees at C appeared blue-green.

Figure 6-214.--A black-and-white reproduction of a color-infrared mapping photograph of swamp and marsh areas in Mingo National Wildlife Refuge near Puxico, Mo.

Figure 6-215, a forward oblique photograph of the same area, also suggests slight differences in moisture levels. Notice the slightly lighter tone exhibited in the area just to the right of A. Apparently there has been an increase in water levels since 1974 when the photograph shown in figure 6-214 was obtained. The increased water levels have increased the size of the wetland area which existed in 1974.

Figure 6-215.--Low-level photograph of swamp area in Mingo National Wildlife Refuge near Puxico, Mo.

Site No. 32 (Swamp and Marsh)
 Location: Wappapello
 Wayne County, Missouri
 Geographic Coordinates: 36°58'N
 90°23'W

Located approximately 6 miles west of the Mingo National Wildlife Refuge lies Wappapello Lake--actually it is a reservoir since this water body was formed following the construction of a dam on the St. Francis River near Wappapello in 1941. Many of the upper reaches of the reservoir now exist as Forested and Nonforested Wetland areas. Site 32, noted by the circle on figure 6-216, illustrates the wetland nature of just one of these areas. Notice the dark gray tone of the Forested Wetlands area in the southwest quadrant of the circle. Also notice the lighter gray tones of adjacent deciduous trees.

Figure 6-217 provides a closer view of the area. Note the difference between the Forested Wetland vegetation at A and B as compared to the Nonforested Wetland area at C.

At the time of this photograph, September 1980, water level of the reservoir was down somewhat. Accordingly, some of the areas, such as just above the B and below the A in the photograph, were not water covered. Although they can be seen more clearly on the original large-scale color photograph, these areas can be identified as the lighter gray areas on this photograph. Marsh areas, at C, appear as even lighter gray areas on the photograph.

Figure 6-216.--Forested Wetlands on upper reaches of Lake Wappapello reservoir west of Wappapello.

Figure 6-217.--Oblique photograph of forested wetlands near Wappapello.

Category 62--Nonforested Wetland

Category	Description.	Nonforested
Wetlands	are areas dominated by herbaceous wetland vegetation or are nonvegetated. In Missouri, these areas include fresh marshes and nonvegetated flats. As suggested in the introductory comments, the Nonforested Wetland category accounts for only one-third of the State's 66,862 acres of wetland. Of this amount, approximately 20,000 acres, almost half is situated in numerous reservoir hollows. The remainder occurs mostly in alluvial flood plains of the Mississippi and Missouri Rivers.	

Environmental Considerations. As with Forested Wetlands, Nonforested Wetland areas are not pollution sources. Likewise, since Nonforested Wetland areas are often situated adjacent to Forested Wetland areas, the environmental consideration comments presented earlier for Forested Wetlands hold for Nonforested Wetlands as well. Therefore, no further comments are presented here.

Interpretation Keys. Site 31, in southeast Missouri, and site 82, in northwest Missouri, illustrate the types of Nonforested Wetland areas found in the State.

Site 31 (Marsh)
 Location: Puxico
 Stoddard County, Missouri
 Geographic Coordinates: 36°59'N
 90°10'W

Figure 6-214, presented earlier in the descriptions for Forested Wetland, identifies the area of the Mingo National Wildlife Refuge to be described here. Water levels have increased since 1974 and, consequently, the area immediately below point A in figure 6-214 now exists as Nonforested Wetland. Figure 6-218, a 1980 photograph of the same area, illustrates the surface appearance of a Nonforested Wetland area. Note the overall mottled tone of the area. The lighter areas at A and B are small water areas, the darker areas at C and D are Forested Wetlands. The remaining nonvegetated area is Nonforested Wetland.

Figure 6-218.--Oblique photograph of Nonforested Wetland in Mingo National Wildlife Refuge near Puxico, Mo.

Site No. 82 (Nonforested Wetland)
Location: Mound City
Holt County, Missouri
Geographic Coordinates: 40°04'N
95°15'W

Site 82, located approximately 4 miles south of Mound City, is located near the southern end of the Squaw Creek National Wildlife Refuge. Figure 6-219, taken in 1975, shows the area at a time of relatively high water levels. Notice the light gray tone of the water area. In contrast, figure 6-220, taken in September 1980, was obtained near the end of a prolonged drought. Notice how aquatic vegetation has replaced much of the water area that existed in 1975. Also note the overall mottled appearance of the area. The mottled

appearance results from differences in algal growth and herbaceous vegetation. The complete lack of woody vegetation in the area should also be noted since this rarely occurs in Missouri.

Figure 6-219.--Mapping photograph of Nonforested Wetland area near Mound City, Mo.

Figure 6-220.--1980 Oblique photograph of Nonforested Wetland area near Mound City, Mo.

LEVEL I, CATEGORY 7--BARREN LAND

Barren Land is land with limited ability to support plant life with less than one-third of the area in vegetation or other cover. In general, it is an area of thin soil, sand,

or rocks. Vegetation, if present, is widely spaced and scrubby. Barren Land is more often found in nature; however, land also may become barren because of man's activities. The Level II categories of Barren Land are: Dry Salt Flats; Beaches; Sandy Areas Other Than Beaches; Bare Exposed Rock; Strip Mines; Quarries and Gravel Pits; Transitional Areas; and Mixed Barren Land. Barren Land categories found in Missouri are Sandy Areas Other Than Beaches (mostly islands and sand bars created by the currents in the larger rivers of the State), Strip Mines, Quarries and Gravel Pits, and Transitional Areas.

The geologic structure of Missouri allows mining of coal in the northern portion of the State, while Quarries and Gravel Pits occur throughout the State.

When land clearing occurs, either in rural or urban areas of the State, and the former or future use of the land cannot be discerned, the area is said to be in transition. Accordingly, in order to avoid inferential errors in classification, it is considered to be a Transitional Area. This transitional classification is also used when forest land is cleared for agriculture, wetland is drained for development, or where areas become temporarily bare, such as construction for highways, residences, shopping centers, industrial sites, or suburban and rural residential subdivisions. Land areas altered by filling, such as sanitary landfills, are also included in the Transitional Area category. These areas in Missouri are mostly forest lands converted for agriculture purposes and areas cleared for new construction.

Category 73--Sandy Areas Other Than Beaches

Category Description. There are approximately 4,000 acres of Sandy Areas Other Than Beaches in Missouri. Most of these sandy areas occur in the channels and banks of the Missouri and Mississippi Rivers, and are formed by sand deposited by their currents. These sandbar islands and tow heads are in a constant state of change--every time the current increases, they are subject to being washed away, and the sand deposited in another location. Because of this instability, vegetation does not have a chance to become established.

Environmental Considerations. Sandy Areas Other Than Beaches, formed by natural process, are not a source of pollution.

Interpretation Keys. The following site indicates the types of areas to be delineated under this category.

Site No. 24 (Sandbar)

Location: 10 miles northeast of Hayti
Pemiscot County, Missouri

Geographic Coordinates: 36°20'N
89°36'W

Figure 6-221, a mapping photograph taken in 1974, shows an area in the Mississippi River channel which would be delineated under this category. Because of their inherent instability, the size and shape of the islands, sandbars, and tow heads are in a constant state of change. Since vegetation hasn't had a chance

Figure 6-221.--Sandy area along the Mississippi River.

Figure 6-222.--Low-altitude oblique photograph of unstable sandy area in Mississippi River.

to become established, these areas are much lighter in tone than the surrounding areas. The instability of this feature is shown in figure 6-222, a low-altitude oblique photograph taken in 1980 of the same area shown in figure 6-221. The photograph shows the light-toned sandy areas in the river and adjacent to the dark-toned shoreline.

Category 75--Strip Mines, Quarries, and Gravel Pits

Category Description. Surface mining activities that have significant surface expressions are included in this category. Vegetative cover and overburden are removed to expose deposits of extractive material such as coal, limestone, iron ore, or copper. Quarrying of stone and the recovery of sand and gravel also result in large open pits. All surface expressions of this type of mining, including active, inactive, and unreclaimed quarries and gravel pits, are included in this category. When other land use or land cover types have been established, these areas are no longer included in this category. Missouri contains approximately 75,177 acres of land in category 75.

Environmental Considerations. Strip mines, quarries, and gravel pits are often a source of significant pollution. Extraction of minerals is often accompanied by careless disposal of spoil materials containing heavy metals and toxic chemicals. Runoff from these waste products may sterilize local soils and contaminate surface and ground water. Surface runoff can collect large concentrations of sulfur and iron resulting in "acid drainage."

Strip mining activities and their associated removal of topsoil increase the erosional potential of an area and may result in increased sediment loads in nearby streams.

Quarries and gravel extraction activities can create excessive noise levels and lower air quality. The use of heavy machinery, vehicles, and intermittent blasting results in increased local noise levels. Dust and debris, caused by heavy machinery and crushing operations, affect local air quality and can create health hazards to nearby residents.

Improper reclamation methods, or the lack of them, can create a site which continually affects the environment. These sites, especially quarries, have been used as landfill sites for both residential and industrial wastes, which if not properly controlled may lead to ground-water contamination. Land collapse, subsidence, and increased erosion result in increased loss of land. The drainage

pattern and hydrology of large regions may also be altered, as well as water quality. Removal or burying of topsoil under spoil material also affects the future productivity of extraction sites.

Interpretation Keys. Presented below are examples of a strip mine, quarry, and gravel pit.

Site No. 97 (Coal Strip Mine)
Location: Thomas Hill Reservoir
Randolph County, Missouri
Geographic Coordinates: 39°32'N
92°38'W

Identification features for strip mining are the spoil banks of overburden, the lack of vegetation on active mines, and deep trenches. The last trench in a sequence of strips is usually water filled. The outer edge of the mining area is called the highwall or headwall. Active strip mines use power shovels for stripping overburden or mining.

This strip mine is just south of the Thomas Hill Reservoir in Randolph County, Missouri. The mapping photograph, figure 6-223, shows the layout of the mined area. New mining is occurring at A, a newly reclaimed mine is at B, and an older reclaimed area at C.

Figure 6-223.--Mined area near Thomas Hill Reservoir, Mo.

Figure 6-224 shows mounds of overburden, newly mined coal, and a power shovel removing overburden. The overburden is removed, the coal removed, and the trench where the coal

was extracted then filled with overburden. This process is repeated until the coal deposits are depleted. The ground photograph, figure 6-225, shows a mining shovel in the process of stripping coal. This photograph provides insight into the size of the shovel and the depth of the trenches and excavation.

Figure 6-224.--Strip mining in progress.

Figure 6-225.--Ground photograph of stripping process.

Site No. 22 (Quarries)
 Location: Cape Girardeau
 Cape Girardeau County, Missouri
 Geographic Coordinates: 37°16'N
 89°34'W

The key identifying photographic features of quarries is the large open pits, usually lighter in tone than adjacent areas, with steep walls. An active quarry will have roads to the pit and loading and crushing facilities.

Quarries are open pits where building stone such as slate, granite, marble, and limestone are extracted. The mapping photograph in figure 6-226, shows two quarries used in producing cement at points A and B. These limestone quarries, south of Cape Girardeau, are owned and operated by a cement company. The limestone is removed and transported to a cement plant nearby. The oblique photograph in figure 6-227 shows the layout of the quarry and the roads leading into the quarry area. The ground photograph, figure 6-228, shows the nearly vertical walls and provides an appreciation for the depth of the quarry.

Figure 6-226.--Mapping photograph of two limestone quarries south of Cape Girardeau, Mo.

Figure 6-227.--Low-altitude oblique photograph of quarry area.

Figure 6-228.--Ground photograph of quarry.

Site No. 30 (Gravel Pit)
 Location: Dexter
 Stoddard County, Missouri
 Geographic Coordinates: 36°49'N
 89°58'W

Key identifying features of gravel pits are the light tones and rough-textured areas where gravel is being excavated, lack of vegetation in the areas being worked, and the presence of access roads leading to the area.

The gravel pit shown in figure 6-229 is a mile and a half northwest of Dexter, in south-east Missouri. Topsoil and overburden are removed and the gravel scooped up by shovels and loaded on trucks for hauling to its destination. Many times, gravel pits are only operated during road construction. The absence of vegetation and the rough texture of the excavation area is exhibited on the photograph shown in figure 6-230. This ground photograph also shows the active gravel pit and the depth of the excavation.

Figure 6-229.--Low-altitude oblique photograph of a gravel pit near Dexter, Mo.

Figure 6-230.--Ground photograph of gravel pit near Dexter, Mo.

Category 76--Transitional Areas

Category Description. The Transitional Area category is used for those areas which are in transition from one land use activity to another. This transitional phase occurs when forest lands are cleared for agriculture, wetlands are drained for development, or when any type of land use ceases as areas become temporarily bare preceding construction for future uses such as residences, shopping centers, industrial sites, or suburban residential subdivisions. Land altered by filling, such as sanitary landfills, is also included in the Transitional category.

Environmental Considerations. The Transitional land use and land cover category in urban areas has the same potential pollution sources as the category to which it belongs. Urban, suburban, and rural areas undergoing conversion to residential and commercial uses exhibit the potential pollution sources associated with construction--excessive noise, dust, and debris, and runoff and erosional possibilities. Following completion of construction, the main environmental concern will be surface runoff and possible localized flooding.

A forested area being cleared for agriculture will exhibit pollution potentials similar to a forested area being harvested or a right-of-way being cleared.

Forested areas undergoing conversion to agriculture are usually sprayed with herbicides to kill trees and brush. Effects of these herbicides on wildlife are controversial, and immediately after spraying, runoff can carry these herbicides into nearby streams and other surface water bodies.

Landfills and spoil dumps are also potentially dangerous sources of water pollution. Landfills are often situated in abandoned pits or quarries. If the geologic structure is unfavorable, or the bedrock permeable, ground water can be contaminated by the disposed wastes. Dust, debris, and noxious fumes from decaying waste can lower air quality in these areas and in adjacent communities.

Interpretation Keys. Two sites, one urban and one rural, are presented to illustrate Transitional Areas.

Site No. 20 (Urban Renewal)

Location: St. Louis

St. Louis City, Missouri

Geographic Coordinates: $38^{\circ}39'N$

$90^{\circ}12'W$

The oblique photograph in figure 6-231 shows an urban renewal area in "inner city" St. Louis. Buildings have been removed and future use is unknown, so the area is classified as a Transitional Area. In many urban renewal projects, deteriorating buildings are torn down and modern apartments or civic buildings constructed.

Figure 6-231.--Urban renewal in St. Louis, Mo.

Figure 6-232, a ground photograph, shows some of the buildings in an urban renewal area. These buildings will be removed, and until another land use can be identified, the area is considered Transitional.

Figure 6-232.--Buildings slated for removal in a urban renewal area, St. Louis, Mo.

Site No. 28 (Rural Transition)

Location: Piedmont

Wayne County, Missouri

Geographic Coordinates: $37^{\circ}13'N$

$90^{\circ}30'W$

Site No. 28, four and a half miles north-east of Piedmont, is a Rural Transition area. The trees were sprayed with a herbicide and bulldozed into windrows. The larger trees were used for firewood and the remaining debris either burned or left to rot. The cleared areas are then tilled, fertilized, planted in grass, and used for pasture.

Figure 6-233 illustrates various phases of the transition: forested area at A, cleared area at B, and land already in pasture at C.

Figure 6-233.--Low-level photograph of forest clearing near Piedmont, Mo.

The ground photograph in figure 6-234 shows the pasture, the windrows, and a few scattered trees in the background.

Figure 6-234.--Ground photograph of forest clearing process.

Site No. 19 (Sanitary Landfill)
Location: Peerless Park
St. Louis County, Missouri
Geographic Coordinates: 38°32'N
90°36'W

Landfills are usually located on the periphery of urban areas in abandoned pits, in low-lying areas, or in other areas of low economic importance. The photographic signatures of landfills can be as varied as the landscape itself. A key identifier of landfills is the lack of trees. The landfills are lighter in tone than the adjacent landscape and tend to have a rough texture (because of the constant repositioning of the waste materials and overburden).

Landfills are included in category 76, Transitional. The mapping photograph, figure 6-235, shows a landfill area at A with lighter tones exhibited in the area of disturbed earth. Also shown, at B, is a drive-in theater which should be placed in land use category 12.

Figure 6-235.--Landfill area, St. Louis County, Mo.

Figure 6-236 shows the inverted "L-shaped" landfill area with its various gray tones and rough texture. When the area is filled to capacity, it will be leveled and developed for another land use such as commercial or residential.

Figure 6-236.--Low-altitude photograph of landfill area near Peerless Park, Mo.

SECTION 7: LAND USE AND LAND COVER TABULATIONS FOR MISSOURI

The graphic maps of land use and land cover, and associated maps, can be used to tabulate the distribution of land use and land cover categories for various regions of concern (e.g., land use by county). Manual methods of computing acreage statistics from maps (e.g., random dot grid counting) are often effective for small project areas, but cannot be used economically over large regions.

In order to meet the need for acreage statistics of large regions, computer methods are used to calculate and cross-tabulate map data. To do this, lines from the maps representing boundaries which separate adjacent polygons must be converted into a computer-readable or digital form. Specialized computer equipment, referred to collectively as digitizers, have been developed to facilitate the conversion of data from graphic to digital form.

There are many varieties of digitizers and methods of representing the map data in a computer. Very often, lines on the map are approximated by line segments defined as a series of x,y coordinates. A group of line segments, or vectors, define closed polygon areas corresponding to polygons on the maps. While polygons on the political units outline counties, polygons on the land use and land cover map outline areas with homogenous land use or cover characteristics. Associated with each polygon is an attribute code. For example, the land use and land cover attribute code "11" describes a homogeneous area of residential land use. Together, the x,y coordinates and associated attributes form a basic unit for computer processing. Once the map information is digitized, the data are processed and edited by a computer system developed by the U.S. Geological Survey. The system, the Geographic Information Retrieval and Analysis System (GIRAS), is utilized to convert and edit the digital x,y-coordinate data (Mitchell, 1977). To compare digital data between maps, the x,y-coordinate data defining the polygon boundaries are converted into uniform sized grid cells. Once gridded, the maps are registered for orientation and alignment (Guptil, 1978).

The land use and land cover maps use a square grid size of 200 meters. This size (4 hectares, approximately 10 acres) is the same as the minimum-sized polygon portrayed on the land use and land cover maps at a scale of 1:250,000.

After the data are converted from x,y coordinates to a regular matrix of grid cells,

subsequent programs merge the grid cells of the individual maps into a single computer file, then count and cross-tabulate the coincidence of attribute codes from two of the maps for each grid cell. In this manner, acreage statistics of land use by county or land use by hydrologic units (or any other associated maps) can be obtained.

The land use and land cover and associated maps for the State of Missouri have been processed through the GIRAS programs and statistical tabulations generated. A listing of the preliminary land use and land cover acreage data by county cross-tabulations follows. The county codes are standard FIPS (Federal Information Processing Standards) codes which are utilized by all Federal agencies. The five digits in these codes consists of a State code (i.e., the leftmost two digits) and a county code (odd numbers only such as 001, 003, 005, etc.). The complete list of codes in ascending order correspond to an alphabetized list of county names for the State (e.g., 29001=Adair county, 29229=Wright county).

Care should be taken in comparing figures from the land use and land cover inventories with other inventories of resources or areal statistical figures. The classification system and methods employed in land use and land cover mapping are explained in this and other documents and it is essential that users understand and critically evaluate the methodologies and data sources used in the various inventories being compared. For example, often-quoted areas of counties may or may not include internal water bodies less than 40 acres, while the land use and land cover maps provide a complete enumeration of all land and water surfaces 10 acres or larger. Estimated areas may be based on manual computations or by more accurate methods employing digitizing. Methodologically, some inventories are based on sampling methods utilizing air photos supplemented with selected field-checks. The land use and land cover maps, by comparison, are based upon precompilation field-checks and interpretation of high-altitude aerial photographs. Basically, differences in inventory results are usually attributable to definable differences for map categories and criteria used in classifying and/or mapping the land surface. Other frequently contributing factors are the dates, scales, and types of photographs used in resource inventory and the scale, methods, and specifications employed in mapping the data. A major objective of this publication has been to aid users in their understanding of the land use and land cover mapping compiled by the U.S. Geological Survey. A better

understanding of land use classification schemes and compilation methods should help users better understand land use and land cover maps and products derived from these maps, such as the areal statistics. Statistical acreage data for the counties and the State of Missouri follow.

State of Missouri Statistical Data--
Land Use By Counties

The following pages present land use acreage values by land use type for each of Missouri's 114 counties and St. Louis City. The number shown beneath each county and St. Louis City is the Bureau of the Census' geographic identification code.

Presented below are the land use codes and their respective explanations. Please note that categories for tundra and perennial ice and snow have been omitted from this list since they do not occur in Missouri. For a more complete listing of the Anderson classification system, refer to table 1-1 in this publication.

SITES IN NUMERICAL ORDER

<u>SITE</u>	<u>LAND USE CATEGORY</u>	<u>PAGE</u>
Site No. 1 (Single-Family Homes)	11	31
Location: Manchester		
St. Louis County, Missouri		
Geographic Coordinates: 38°36'N, 90°31'W		
Site No. 2 (Inner-City Residential)	11	32
Location: St. Louis		
St. Louis City, Missouri		
Geographic Coordinates: 38°36'N, 90°14'W		
Site No. 3 (High-Rise Residential)	11	33
Location: St. Louis		
St. Louis City, Missouri		
Geographic Coordinates: 38°31'N, 90°13'W		
Site No. 4 (Shopping Center)	12	38
Location: Mehlville		
St. Louis County, Missouri		
Geographic Coordinates: 38°31'N, 90°20'W		
Site No. 5 (Hospital)	12	49
Location: St. Louis		
St. Louis City, Missouri		
Geographic coordinates: 38°38'N, 90°16'W		
Site No. 6 (Intermediate School)	12	51
Location: Webster Groves		
St. Louis County, Missouri		
Geographic Coordinates: 38°34'N, 91°22'W		
Site No. 7 (Sports Stadium)	12	47
Location: St. Louis		
St. Louis City, Missouri		
Geographic Coordinates: 38°38'N, 90°12'W		
Site No. 8 (Rolling Mills - Steel)	13	55
Location: St. Louis		
St. Louis City, Missouri		
Geographic Coordinates: 38°37'N, 90°18'W		
Site No. 9 (Barge Building)	13	56
Location: St. Louis		
St. Louis City, Missouri		
Geographic Coordinates: 38°32'N, 90°15'W		
Site No. 10 (Highway Intersection)	14	69
Location: St. Louis		
St. Louis City, Missouri		
Geographic Coordinates: 38°38'N, 90°17'W		

Site No. 11	(Truck Terminal)	14	69
Location:	St. Louis		
	St. Louis City, Missouri		
Geographic Coordinates:	38°31'N, 90°12'W		
Site No. 12	(Railroad Yards)	14	70
Location:	St. Louis		
	St. Louis City, Missouri		
Geographic Coordinates:	38°35'N, 90°12'W		
Site No. 13	(Sewage Treatment Plant)	14	74
Location:	Lemay		
	St. Louis County, Missouri		
Geographic Coordinates:	38°32'N, 90°17'W		
Site No. 14	(Municipal Water Treatment Plant)	14	72
Location:	St. Louis		
	St. Louis City, Missouri		
Geographic Coordinates:	38°45'N, 90°11'W		
Site No. 15	(Industrial and Commercial)	15	75
Location:	Robertson		
	St. Louis County, Missouri		
Geographic Coordinates:	38°46'N, 90°23'W		
Site No. 16	(Mixed Urban or Built-up Land)	16	76
Location:	St. Louis		
	St. Louis City, Missouri		
Geographic Coordinates:	38°38'N, 90°15'W		
Site No. 17	(Forest Park)	17	77
Location:	St. Louis		
	St. Louis City, Missouri		
Geographic Coordinates:	38°38'N, 90°17'W		
Site No. 18	(Cemetery)	17	78
Location:	Mehlville		
	St. Louis County, Missouri		
Geographic Coordinates:	38°30'N, 90°17'W		
Site No. 19	(Sanitary Landfill)	17	109
Location:	Peerless Park		
	St. Louis County, Missouri		
Geographic Coordinates:	38°32'N, 90°36'W		
Site No. 20	(Urban Renewal)	76	108
Location:	St. Louis		
	St. Louis City, Missouri		
Geographic Coordinates:	38°39'N, 90°12'W		
Site No. 21	(Cement Plant and Quarry)	13	57
Location:	Cape Girardeau		
	Cape Girardeau County, Missouri		
Geographic Coordinates:	37°16'N, 89°32'W		

Site No. 22	(Quarries)	75	106
Location:	Cape Girardeau		
	Cape Girardeau County, Missouri		
Geographic Coordinates:	37°16'N, 89°34'W		
Site No. 23	(Orchard)	22	82
Location:	Kelso		
	Scott County, Missouri		
Geographic Coordinates:	37°11'N, 89°33'W		
Site No. 24	(Sand Bar)	73	104
Location:	10 miles northeast of Hayti		
	Pemiscot County, Missouri		
Geographic Coordinates:	36°20'N, 89°36'W		
Site No. 25	(Plantation Pine)	42	94
Location:	New Madrid		
	New Madrid County, Missouri		
Geographic Coordinates:	36°32'N, 89°26'W		
Site No. 26	(Canals)	51	97
Location:	Kennett		
	Dunklin County, Missouri		
Geographic Coordinates:	36°10'N, 90°01'W		
Site No. 27	(Not Used)		
Site No. 28	(Rural Transition)	76	108
Location:	Piedmont		
	Wayne County, Missouri		
Geographic Coordinates:	37°13'N, 90°30'W		
Site No. 29	(Chicken Houses)	23	84
Location:	Bloomfield		
	Stoddard County, Missouri		
Geographic Coordinates:	36°53'N, 89°55'W		
Site No. 30	(Gravel Pit)	75	107
Location:	Dexter		
	Stoddard County, Missouri		
Geographic Coordinates:	36°49'N, 89°58'W		
Site No. 31	(Swamp)	61	101
Location:	Puxico		
	Stoddard County, Missouri		
Geographic Coordinates:	37°01'N, 90°10'W		
Site No. 31	(Marsh)	62	102
Location:	Puxico		
	Stoddard County, Missouri		
Geographic Coordinates:	36°59'N, 90°10'W		
Site No. 32	(Swamp and Marsh)	61	102
Location:	Wappapello		
	Wayne County, Missouri		
Geographic Coordinates:	36°58'N, 90°23'W		

Site No. 33 (Clearwater Lake Reservoir) . . . 53 99
 Location: Piedmont
 Wayne County, Missouri
 Geographic Coordinates: 37°08'N, 90°46'W

Site No. 34 (Not Used)

Site No. 35 (Mine) 13 59
 Location: Bunker
 Reynolds County, Missouri
 Geographic Coordinates: 37°32'N, 91°09'W

Site No. 36 (Metal Processing) 13 60
 Location: Buick
 Reynolds County, Missouri
 Geographic Coordinates: 37°34'N, 91°08'W

Site no. 37 (Mine and Smelter) 13 61
 Location: Buick
 Reynolds County, Missouri
 Geographic Coordinates: 37°34'N, 91°08'W

Site No. 38 (Fish Farm) 24 87
 Location: Montreal
 Camden County, Missouri
 Geographic Coordinates: 37°53'N, 92°31'W

Site No. 39 (Mixed Deciduous and Evergreen Forest
 Cover) 43 95
 Location: Edgehill
 Iron County, Missouri
 Geographic Coordinates: 37°37'N, 90°54'W

Site No. 40 (Small Town CBD) 12 41
 Location: Ironton
 Iron County, Missouri
 Geographic Coordinates: 37°36'N, 90°38'W

Site No. 41 (Orchard) 22 82
 Location: Bonne Terre
 St. Francois County, Missouri
 Geographic Coordinates: 37°55'N, 90°32'W

Site No. 42 (Airport) 14 71
 Location: Vichy
 Maries County, Missouri
 Geographic Coordinates: 38°08'N, 91°46'W

Site No. 43 (Vineyard) 22 83
 Location: St. James
 Phelps County, Missouri
 Geographic Coordinates: 38°02'N, 91°34'W

Site No. 44 (Pasture) 21 80
 Location: Jerome
 Phelps County, Missouri
 Geographic Coordinates: 37°58'N, 91°59'W

Site No.	45	(Auto Salvage Yard)	12	46
Location:	St. Robert			
	Pulaski County, Missouri			
Geographic Coordinates:	37°48'N, 92°09'W			
Site No.	46	(Commercial Strip Development)	12	41
Location:	St. Robert			
	Pulaski County, Missouri			
Geographic Coordinates:	37°49'N, 92°10'W			
Site No.	47	(Golf Course)	17	77
Location:	Fort Leonard Wood			
	Pulaski County, Missouri			
Geographic Coordinates:	37°44'N, 92°05'W			
Site No.	48	(Military Installation)	12	52
Location:	Fort Leonard Wood			
	Pulaski County, Missouri			
Geographic Coordinates:	37°46'N, 92°08'W			
Site No.	49	(Medium Size City CBD)	12	40
Location:	Lebanon			
	Laclede County, Missouri			
Geographic Coordinates:	37°41'N, 92°40'W			
Site No.	50	(Stave Company)	13	62
Location:	Lebanon			
	Laclede County, Missouri			
Geographic Coordinates:	37°40'N, 92°40'W			
Site No.	51	(Garden Apartments)	11	34
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°11'N, 93°19'W			
Site No.	52	(Mobile Home)	11	35
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°11'N, 93°22'W			
Site No.	53	(Shopping Mall)	12	39
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°10'N, 93°16'W			
Site No.	54	(Motels)	12	42
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°15'N, 93°16'W			
Site No.	55	(Suburban Office Building)	12	43
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°11'N, 93°16'W			
Site No.	56	(Federal Hospital)	12	50
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°10'N, 93°19'W			

Site No.	57	(Hospital)	12	49
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°11'N, 93°17'W			
Site no.	58	(University)	12	51
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°12'N, 93°16'W			
Site no.	59	(Regional Fairgrounds)	12	48
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°15'N, 93°18'W			
Site No.	60	(Light Industry)	13	64
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°15'N, 93°12'W			
Site no.	61	(Railroad Yards and Repair Shops)	14	71
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°13'N, 93°20'W			
Site No.	62	(Downtown Airport)	14	72
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°13'N, 93°15'W			
Site No.	63	(Water Treatment Plant)	14	73
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°10'N, 93°13'W			
Site No.	64	(Mixed or Built-up Land)	16	76
Location:	Springfield			
	Greene County, Missouri			
Geographic Coordinates:	37°12'N, 93°17'W			
Site No.	65	(Eastern Redcedar)	42	94
Location:	Bradleyville			
	Taney County, Missouri			
Geographic Coordinates:	36°46'N, 92°57'W			
Site No.	66	(Dam - Hydroelectric)	13	64
Location:	Table Rock Reservoir			
	Taney County, Missouri			
Geographic Coordinates:	36°36'N, 93°19'W			
Site No.	67	(Not Used)		
Site No.	68	(Cropland)	21	81
Location:	Chamois			
	Osage County, Missouri			
Geographic Coordinates:	38°40'N, 91°45'W			

Site No.	69	(State Capitol Building)		12		43
Location:		Jefferson City				
		Cole County, Missouri				
Geographic Coordinates:		34°50'N, 92°10'W				
Site No.	70	(Missouri River)		51		96
Location:		Jefferson City				
		Cole County, Missouri				
Geographic Coordinates:		38°35'N, 92°11'W				
Site No.	71	(Nuclear Power Plant)		13		64
Location:		Reform				
		Callaway County, Missouri				
Geographic Coordinates:		38°45'N, 91°45'W				
Site No.	72	(Auto Salvage Yard)		12		46
Location:		Columbia				
		Boone County, Missouri				
Geographic Coordinates:		39°58'N, 92°26'W				
Site No.	73	(Orchard)		22		83
Location:		New Franklin				
		Howard County, Missouri				
Geographic Coordinates:		39°02'N, 92°43'W				
Site No.	74	(Reforested Strip Mine)		41		92
Location:		Windsor				
		Henry County, Missouri				
Geographic Coordinates:		38°34'N, 93°35'W

PREFACE

This study was conducted under DA Projects 4A161102B52C, Task C, Work Unit 0008, "Photo Interpretation Logic," and 4A762707A855, Task C, Work Unit 0034, "Photo Interpretation Logic and Feature Extraction." The study was done under the supervision of Dr. Jack N. Rinker, Team Leader, Center for Remote Sensing, and Dr. Robert D. Leighty, Director, Research Institute.

Special thanks are extended to Ms. Barbara Jayne, Liaison Office, for preparing several of the illustrations in Appendixes A and I of this report.

COL Edward K. Wintz, CE, was Commander and Director and Mr. Walter E. Boge was Technical Director of the Engineer Topographic Laboratories during the report preparation.

AIR PHOTO ANALYSIS

Jack N. Rinker

INTRODUCTION

The more commonly used image forms are photography, radar, LANDSAT, infrared thermal, and passive microwave. With the exception of LANDSAT, these systems are used in both aircraft and satellites for obtaining general and specific information about the atmosphere, the terrain, and the oceans, as well as for detecting special features and targets. From the standpoint of gathering information about the terrain in terms of identities, composition, and properties, the most frequently used instruments are stereo aerial photography, radar, and LANDSAT. Information can be extracted from these images in three general ways: (1) manual; (2) interactive, which includes using knowledge-based systems and supervised digital classification procedures, such as used with LANDSAT; and (3) automatic, which includes pattern recognition and unsupervised digital classification techniques. Obviously, there can be mixes of these three.

In this report, the term **manual** denotes the minimum of mechanical assistance, i.e. the analysis depends on the images, eyes, mind, hand lens, and pocket stereoscope. The terms **machine** or **machine assisted** will be used to designate those procedures commonly referred to as automatic pattern recognition, digital analysis, and man/computer interactive analysis. The automatic procedures are restricted to a few very obvious types of feature discrimination, and at present, these procedures are of little practical use and are not likely to be significantly improved in the foreseeable future. On the other hand, interactive techniques are constantly being developed and have far less restrictions than do the automatic procedures. Also, interactive techniques based upon digital classification of spectral data will probably improve significantly in the future as satellites with more and narrower spectral band passes are launched.

At present, however, the manual analysis of stereo aerial photography represents the state of the art insofar as obtaining reliable and detailed information about any given region of the earth in terms of its composition, properties, use, and probable response to stress, i.e. items that are of direct and practical use to engineering and military applications. Whatever use of the terrain is envisioned in terms of building on it, tunneling through it, extracting from it, moving over it, or seeking cover and concealment, certain pieces of information are needed before decisions can be made. These pieces can come from several sources, including personal knowledge, field and laboratory work, maps and literature, and remote sensing, especially in the form of stereo aerial photography.

In general, image analysis and interpretation techniques tend to fall into one of two broad overlapping categories, which, at the extremes, can be defined as procedures associated with detecting, targeting, and monitoring on the one hand, and procedures associated with deductive and inductive reasoning on the other. At present, applying machine and machine-assisted procedures tends to be limited to the tasks of detecting and monitoring.

Targeting, detecting, and monitoring techniques require that the feature, whatever it is, have some characteristic that is different from its background and that, hopefully, cannot be confused with any other object in the field of view. These differences can be based on such things as shape, size, arrangement, color, spectral absorption and reflection, temperature, etc. Applications that fall into this category include: (1) detecting discrete objects such as roads, airports, dams, vehicles, specific crops, number of lakes per area, etc.; (2) detecting changes in patterns; (3) detecting and mapping flood boundaries, flood and storm damage, insect damage, diseased crops, alteration zones, and camouflage sites; and (4) estimating values such as crop yield, percent of tree cover, etc. For some of these applications, other remote sensors (radar, thermal, LANDSAT) can be of more use than air photos. As a group, however, it is these applications that have provided the basis for whatever success has been achieved by machine techniques, and of these, those that are based on distinguishing colors and color changes (spectral signatures, multiband, etc.) have had more successes with machine and machine-assisted procedures than have those that rely on identifying shape and arrangement. Because future systems will have more spectral channels and narrower bandpasses, there will be an increase in the ability to discriminate various objects and surfaces. It remains to be determined, however, if there will be a corresponding increase in the ability to identify these various objects and surfaces.

Deductive and inductive reasoning procedures produce information that is broader in scope, and more complex in content, than that derived by using targeting and detecting techniques. These procedures are directed towards gaining as much information and understanding as possible about the area in question, i.e. the nature of the materials in terms of structure, composition, and properties; the characteristics of the vegetation; the climatic factors; and man's activities. This information forms what can be called an environmental data base, which can then be interpreted with respect to such problems as resources inventory (including ground water), regional planning, site selection and evaluation, cross-country movement, and prediction of environmental impact as the result of any given action. This procedure of analysis relies upon the inductive and deductive evaluation of various lines of converging evidence derived from the visual examination of image patterns. Insofar as determining the nature of the terrain in terms of identities, composition, and conditions, the most important pattern elements are those associated with three-dimensional shapes; thus, the mainstay of this type of analysis is stereo aerial

photography, and as yet, three-dimensional shapes do not lend themselves to machine evaluation. It is a manual task and the burden of the work falls on the individual. It is a task, however, that might benefit, at least in part, from the use of interactive systems. The benefit in this case would be in using a technique that enables a less skilled and less experienced individual to proceed down paths of reasoning that a skilled and experienced analyst would follow intuitively. Although one might argue that each pattern element, i.e. landform, drainage, soil, tone, etc., can serve as a target and thus lend itself to machine applications, the fact is that most natural pattern elements cannot be held to the rigid and exact descriptions needed in automatic targeting and detecting procedures. The important pattern elements of landform, drainage, and gully cross sections are associated with shape, and these shapes are neither exact nor invariant, but undergo changes as a result of slight variations in composition or in climate. Massive beds of limestone do not have but one shape; neither do beds of sandstone, deposits of basalt, nor patterns of a given drainage type. Although the shapes of massive beds of similar limestone are not identical, neither will they be completely dissimilar, i.e. they will have at least some characteristics in common. It is more a matter of theme and variations. The fact that they are not exact replicas indicates that there are slight differences in composition, conditions, or climate. A skilled and experienced analyst recognizes the similarities and differences and, on the basis of judgment and inference, makes a prediction as to what group of shapes this particular pattern belongs to and what material or conditions it most likely represents.

The photo analysis procedure used by the Center for Remote Sensing (CRS), and on which it concentrates its research, is based on the published and unpublished notes of Robert E. Frost* and other staff members of the School of Civil Engineering of Purdue University during the late 1940's and early 1950's.^{1,2} At that time, the procedure was directed towards the photo interpretation of soils and rocks for engineering purposes, and still retains much of that perspective. Over the years CRS and its predecessor organizational units have tested, evaluated, augmented, and modified the procedure by field research and application projects in many areas of the world. The application tasks included engineering and geologic problems ranging from locating engineering materials through site selection for roads, airports, etc., to large Department of Defense (DOD) applications such as the layout of Thule Air Base, Greenland, (done by Robert E. Frost and some of his staff while at Purdue University) or the environmental data base prepared over much of Wisconsin for the Navy Project Sanguine. Included in these

*Mr. Frost currently works for the U.S. Army Engineer Topographic Laboratories (ETL).

¹R.E. Frost. 1950. *Evaluation of Soils and Permafrost Conditions in the Territory of Alaska by Means of Aerial Photographs*. Prepared by the Purdue University Engineering Experiment Station for the St. Paul District, Corps of Engineers, Department of the Army.

²R.E. Frost, J.G. Johnstone, O.W. Mintzer, M. Parvis, P. Montano, R.D. Miles, and J.R. Shepard. 1953. *A Manual on the Airphoto Interpretation of Soils and Rocks for Engineering Purposes*. School of Civil Engineering and Engineering Mechanics, Purdue University, West Lafayette, Indiana.

DOD applications were smaller projects associated with insurgency, tunnels and caves, defoliation, etc. In addition, this photo analysis procedure has formed the basis for a series of intensive short courses that have been presented within the U.S. and Latin America.

This method of photo analysis relies on associating numerous threads of converging evidence and requires an understanding of the origin and relation of landscape features, as well as the relation of these features to their aerial formed images. In practice, the procedure is divided into two phases, the regional analysis and the local analysis.

For the regional analysis, relatively small scale imagery is used, such as LANDSAT or photo index sheets, preferably both. The purpose of the regional analysis is to establish the broad frame of environmental conditions that are contained within, as well as around, the area of interest. In this part of the analysis, general decisions are made as to boundaries separating economic pursuits, vegetation classes, landform units, and soil characteristics.

For the local analysis, effort is focused on the landscape pattern units via larger scale stereo imagery, which provides the detail needed to fill in the regional information and to make decisions as to types and conditions of materials. A number of photo scales are available, e.g. 1:20,000, 1:40,000, 1:60,000, and 1:120,000. In recent years, the tendency has been to take aerial photography at the smaller scales, especially 1:40,000 and 1:60,000. When available, the larger scale of 1:20,000 is usually preferable because it is a very good compromise in terms of the amount of photography needed to cover an area and the size of pattern detail that must be seen. Much of the fine structure such as gully cross section, and subtle changes in gully gradient or concavity of slopes, is not readily seen in the smaller scales, i.e. < 1:40,000. In some instances, color photography is also available, either as normal color or false color. Although it is certainly usable, color photography is not needed for a general photo analysis and does not contribute enough additional capability to justify the increased cost. For certain detection tasks, however, such as some vegetation mapping, locating diseased vegetation, or locating wetlands boundaries, it is more useful than panchromatic photography.

Reduced to the simplest of terms, the principles for this procedure, originally stated in Frost,³ can be expressed as follows:

³R.E. Frost, J.G. Johnstone, O.W. Mintzer, M. Parvis, P. Montano, R.D. Miles, and J.R. Shepard. 1953. *A Manual on the Airphoto Interpretation of Soils and Rocks for Engineering Purposes*. School of Civil Engineering and Engineering Mechanics, Purdue University, West Lafayette, Indiana.

1. An air photo is a pictorial representation of the various features within the landscape and is composed of pattern elements that serve as indicators of materials, conditions, and events that are related to the physical, biological, cultural, and climatic components of the landscape.

2. Similar materials and conditions in similar environments produce similar patterns, and unlike materials and conditions produce unlike patterns.

3. The type, quantity, and quality of information that can be obtained by photo analysis is proportional to the background, knowledge, skill, and interest of the analyst.

The foundation of this method rests in principle 2, i.e. similar materials and conditions in similar environments produce similar patterns, and unlike materials and conditions produce unlike patterns. There are many patterns to be evaluated and most of them can be evaluated only by stereo viewing. Based upon the statement in principle 2, one can reason that if the patterns are uniform across an image, then the materials and conditions, whatever they might be, will be uniform throughout that area. If any pattern element changes, e.g. gully cross section, gradient, soil tones, hill shape, vegetation texture, etc., then either the materials or the conditions, or both, must have changed. In some cases, specific pattern elements are uniquely related to the identity of a material, or to a given condition. Also, many of the pattern elements must be evaluated in relation to climate and season as these can cause considerable modification.

The analysis of any given pattern involves at least three steps: first, identification; second, description; and third, signification. The last step is the most important and, without doubt, the most difficult, requiring more in terms of knowledge, experience, and judgment than does either of the first two steps.

Identification is the act of recognizing any given pattern and either tracing out its domain or otherwise using it during the analysis. By definition, the pattern must be different beyond that boundary; therefore, there must be a corresponding change in materials or conditions, or both, as that boundary is crossed. Depending on the pattern being considered, the boundary might enscribe a group of items of the same shape, a surface of uniform tone and texture, a drainage net of uniform spacing and arrangement, or some other identifiable property. The boundary denotes the location of a change; it does not necessarily give information about the contents within.

The next step is to describe in detail the characteristics of the subject pattern in terms of size, shape, spacing, arrangement, symmetry, etc. The description is then evaluated in terms of its significance, the last step. Each pattern element signifies, or suggests, something about the nature of the material in terms of its characteristics, its condition, or its probable composition.

Although these points about observation, deduction, identification, and significance seem obvious, if not trivial, they are important. First, they are interwoven to some extent throughout all applications of the photo analysis procedure. Second, an understanding of these issues sheds light on the very real problems associated with applying photo analysis to stated Army needs, evaluating remote sensing techniques against specific tasks, developing classification systems, and determining skill levels required. There are, of course, many patterns yet unknown as well as many patterns that are not understood. There are many different pattern elements within an air photo, and in order to apply the stated principles in an effective manner, one must follow some sort of systematic procedure to ensure that all elements are considered. The scheme that we currently use classifies the pattern elements into the following categories: landform, drainage (plan and elevation), erosion, deposition, vegetation, cultural, photo tones and texture, and special. Each of these factors provides some information as to the nature of the terrain and its materials in terms of their physical properties and probable composition, and it is this sequence of classes that forms the basis for a systematic procedure for the analysis of terrain features by use of air photos. This procedure has a number of practical advantages.

1. **Simplicity.** Although the concept of photo analysis is simple, it does not follow that skill, experience, judgment, and knowledge are not needed to implement it. As is frequently the case, the implementation of a simple procedure requires more skill, capability, and judgment than does the implementation of a complex procedure. Simple procedures rely on the individual to correlate details and render judgment; complex procedures incorporate the details and sequential steps and rely on an individual following them. Simple procedures, however, provide versatility and set the basis for universality, economy, and rapidity.

2. **Universality.** The nature of the various patterns in terms of cause and effect provides a basis for obtaining information about the terrain independent of location or, indeed, without the need of knowing the location represented by the imagery. Although auxiliary information in terms of location, physiographic area, climate, etc., can be useful, and although the location is probably always known, these items are not necessary to the task of obtaining information from the photos.

3. **Economy.** Air photo prints are among the more economical, if not the cheapest, of imagery forms available, and they are readily at hand in the commercial world as well as within the military structure. As a minimum, the needed equipment consists of a large hand lens and a pocket-type folding stereoscope.

4. **Rapidity.** As yet, no other procedure can match the quality and quantity of information that can be derived in a given time frame. An experienced team of four to five individuals can produce an environmental data base of an area some 20 by 40 miles complete with overlays, text, and interpretation with respect to a problem, and do so in 15 to 20 working hours.

Because the pattern sets of landform, drainage (plan and elevation), erosion, deposition, vegetation, cultural, tone and texture, and special are the conveyors of information about the terrain, they are the basic components of this procedure of manual analysis of aerial photography. In the following section, these groups will be discussed in summary form, but with enough information to at least define them and explain why they are important and how they are used. As information and research results accumulate, some of these sections will be expanded into individual reports.

PATTERN ELEMENTS

LANDFORM. This pattern refers to the shape, size, arrangement, and orientation of any given surface feature and its location within, and relation to, the surrounding area. It is the most important of the pattern elements because it is directly related to the nature of the resident material in terms of composition and properties. An understanding of landform development makes it possible to bound areas of similar materials and conditions, determine their physical characteristics, and at times predict their composition and texture. Such events as deposition, sedimentation, and volcanism constantly add new materials to the earth's surface. Other events, such as folding, uplifting, or lowering of the ocean levels constantly elevate these materials above the base level; whereupon other events begin immediately to reduce the mass back to its base level. The force of gravity, coupled to the energy of flowing water or wind, and to the action of freeze and thaw, or of water as a solute, does this by removing bits and pieces and carrying them to the lows. But the bits and pieces are removed in a way unique to the material and action combination. As a result, the landscape shows a variety of shapes and arrangements. Within this variety, however, there are such firm relations between cause and effect that one can frequently glean from the stereo photo patterns of landform some idea of what went on, what is going on, and what is present in terms of general composition and physical properties.

The chemical and physical properties of a substance depend on the identities of the atoms, and collection of atoms, that make up the molecules of the substance. In the case of rocks and their detrital material, these molecules are called minerals. Different minerals have different physical and chemical characteristics with relation to hardness, plasticity, porosity, permeability, solubility, and thermal expansion. As a result, different rocks and soils exposed to the same action, or the same material exposed to different actions, will develop different patterns of shape, tone, and texture. Because the forces that do the shaping vary with climate, the same material can have different landforms in different regions. Limestone, for example, can be a hard, durable, and resistant rock. It is, however, soluble in dilute carbonic acid formed from available water and carbon dioxide from various sources. In a warm region with an abundance of water, limestone can be the easiest to degrade of the resistant materials and, therefore, can be a valley former. In an arid region, without water to act as an agent of dissolution, the limestone can be the hardest and most resistant rock in the area. It can form the highs, such as hills or ridges, or serve as a protective cap over less resistant beds. In either case, other pattern elements are usually present that support the concept for the material being a sedimentary rock, and most probably limestone. Because of these firm relations, shape or landform is considered to be the most important of the pattern elements, and wherever the shape changes in any aspect, there is the basis for a corresponding change in materials or conditions, or both.

In this part of the photo analysis, areas are outlined in which the terrain elements within are uniform in shape, size, spacing, arrangement, and orientation. Wherever any aspect of landform changes, there is a basis for a boundary denoting some change in materials or conditions, or both. The area of study represented by the stereo photography might contain but one shape, a plain for example. Thus, one would expect a uniformity in composition throughout that area, i.e. the surficial soils would be essentially the same all over. On the other hand, the study area might contain three landform units, all hills. Within each bounded area the hills are the same, but each group differs from the others. Thus, the bounded areas also represent three different materials, or material/condition combinations.

Each landform unit must be described in terms of shape, size, spacing, arrangement, symmetry, slope, angularity, etc., and then evaluated with reference to the significance of these observations. Profiles should be drawn across the stereo field of view. As the analysis develops, these can be converted into possible geologic cross sections. The complexities of landform classification found in most texts and articles are beyond the needs of this type of analysis, at least for the present. However complicated, the units can be assigned into one of four general categories: plains, hills and mountains, basins and valleys, and escarpments.

Plains. This category refers to a flat surface, large or small, but not necessarily level or with any elevation restrictions. Such surfaces can be established by depositing sediments in low areas, by large lava flows, by exposure of flat-lying intrusive masses, and by grinding or eroding an irregular surface into a flatter one. In size such plains range from small stream terraces to large regions, such as the Great Plains of the United States, or extensive areas of the Precambrian Canadian Shield. Identifying a surface as flat depends on one's regional point of view and on the scale of the imagery. Many topographic variations exist that can appear hilly to a person on the ground but which, nevertheless, are properly classified as plains. This has led to descriptors for plains such as rolling, undulating, pitted, dissected, etc. At small scales, such as those associated with LANDSAT (1:250,000 to 1:1,000,000), most of the Canadian Shield would be mapped as a plain. At air photo scales of 1:20,000, much of the shield area would show as rugged terrain, and it would most likely be mapped as containing several landform units, and possibly none of them would be classified as a plain. From the standpoint of this type of photo analysis, the significance of a plain is that it suggests deposition of some sort, for that is the easiest way to establish a plain. This is usually by means of sedimentation, i.e. a settling out of material suspended in a water-filled basin or trough, either marine or fresh. Deposits such as alluvial fans have a hill-like profile across their width and are not usually considered to be plains. On a large fan, the imagery might

show only a portion of it, and that portion could be classified as a plain. In any event, the significance is a suggestion of the presence of sedimentary rocks or granular material. Although a lava flow can form a plain, other pattern elements would prevent it from being considered as a sedimentary unit or granular deposit.

Hills and Mountains. This category refers to elevations above the base level of the region in question. The distinction between hill and mountain is a blurred one that is based mostly on local usage, or personal preference. The *Glossary of Geology*⁴ gives 300 meters (1000 ft) as the elevation difference between base and summit that divides the two classes, i.e. under 300 m, it is called a hill, and over 300 m, it is called a mountain. Hills can be formed by depositing material on top of the ground; by sub-surface material pushing the surface up, or pushing up through the surface; by forcing the surface into a series of ripple-like folds; by faulting; and by cutting into, or eroding into, a previously flat surface. Each of these processes results in patterns that are suggestive of origin, and consequently of materials. A flat-lying area of sediments can be called a plain only so long. There comes a time when the forces of erosion have so extended and deepened the valleys and have removed so much of the original surface that that which is left can only be classified as hills. These hills, however, will still retain clues as to their sedimentary nature. Whatever the source of the hill, or mountain, the characteristics of its shape provide clues as to its origin, which, in turn, serve as indicators of its physical properties, such as hardness, perviousness, cohesiveness, etc. At this point, one can frequently make an inference, based on experience and judgment, as to possible composition.

In general, hills and mountains that are made of hard, durable, igneous and metamorphic rocks have sharp, angular, and irregular outlines in both plan and elevation. They are devoid of symmetry and do not show finger-like extensions or ridges. Granitic rocks can show a softening of the angularity, but it is not a roundedness easily confused with the rounded slopes of soft materials. The surficial characteristics of igneous and metamorphic rocks depend on the molecular groups or minerals involved, the climatic region, and the amount of fracturing. In large masses of granite that are not fractured, or in which the fractures have been sealed by other materials and forces, the whole can have a smooth rounded shape. If the mass is intensively fractured, then the pattern is more jagged and can contain needle-like features. Usually, granite rocks have a lumpy surface

⁴Am. Geol. Inst., 1972. *Glossary of Geology*. Washington, DC.

texture. The pattern of a lumpy surface, or of needle-like spires, is not in itself sufficient to identify the rock type, because similar patterns can be found in other rocks under other conditions. For example, some tropical limestone weathers to present a lumpy surface, and needle-like spires can be found in massive beds of limestone and in columnar basalt.

The sedimentary rocks — sandstone, shale, and limestone — have other shape characteristics. The fact that these rocks are formed by a continuing, or sequential, deposition of suspended matter causes them to have a layered nature. These layers, or beds, can be of one type rock, or they can be different rocks; and the layers can be thin, i.e. measured in millimeters, or they can be thick and measured in tens or hundreds of meters. This originally horizontal, flat-lying, layered structure can be uplifted, tilted, folded, fractured, and weathered in all sorts of complex ways, but not all the basic characteristics associated with a layered system will be destroyed. Flat-lying and nearly flat-lying beds that have been dissected by erosion develop hills with ridges, or finger-like extensions, that have symmetrical profiles across them. If the layers are made of sandstone or limestone and are thick, i.e. measured in tens or hundreds of meters, the hills will be blocky with steep, if not vertical, sides. Clay shale beds do not have this thickness, and even if they were thick, the hills would show a rounded profile because of the cohesive nature of clay. As the beds become thinner, the massive blocky structure is lost and other slope shapes develop. If a more resistant material is interbedded in the sequence, a stair-step pattern becomes evident. With thinner beds, the steps, if present, become imperceptible in conventional stereo aerial photography, with the result that the hills have rather smooth-looking slopes. The shape of the slope can also be a pattern element that is indicative of the nature of the materials. If the rocks are thinly interbedded sandstones and shales, the slopes tend to have a uniform gradient down most of the hillside. If the rocks are thinly interbedded limestones and shales, the slopes tend to become concave and exhibit a noticeable flare in the lower third of the hill. In general, sandstones develop sharper ridge lines and more angular patterns than do limestones. If a sandstone is very soft, or contains a significant amount of calcium carbonate, it begins to resemble the landforms developed in limestones. Clay shales show the ridge-like extensions associated with flat-lying sedimentary rocks, but being made of soft cohesive and plastic material, the profiles and contour lines tend to be very gently rounded.

Sedimentary beds that are tilted retain many of the characteristics mentioned earlier, i.e. blockiness, stair-steps, etc.; but, in addition, they develop other landforms. Sooner or later the edges of tilted beds will become exposed and will weather and erode according to their composition. The resulting landform is a series of parallel V-shaped ridges that form a sawtooth-type profile across them, which can be either symmetrical or asymmetrical. A symmetrical profile suggests that the beds are dipping at 45° . The ridges, which represent the length of the exposed beds, can be very long, i.e. kilometers.

Basins and Valleys. These structures refer to depressions that are sufficiently large to provide a significant separation between the adjacent higher elevations. Basins do not have surface outlets, can vary greatly in size and shape, and are produced by several events, including folding and erosion. Whatever the cause, it is an area in which sediments can accumulate. The characteristics of a basin can provide information as to composition of the parent material and the forces that brought the depression into being. Valleys usually have surface outlets and are usually elongate. Most frequently, they are caused by stream erosion, but are also produced by moving ice, folding, faulting, and solutioning. Solution valleys, such as in limestone areas, can be fairly extensive and complex and yet not exhibit a surface outlet. Although valleys provide passages for the transport of water and materials, they can collect sediments by a variety of processes, e.g. fluvial, glacial fluvial, etc. The shape characteristics of a valley provide information about parent materials and the nature of the processes that created the valley.

Escarments. Escarpments are usually long, fairly continuous steep slopes or cliff faces that separate some landform units. They also exist, however, as broad, gently sloped bands that most frequently result from faulting and subsequent erosion. Although they are not usually considered as a type of landform, they are included to indicate that, where they do occur, they merit evaluation. They are important pattern elements, and their characteristics can provide information about composition and the nature of the causative forces.

Refer to appendix G and report ETL-0261⁵ for further information about landform patterns for some rock types.

DRAINAGE. This refers to all drainageways, including standing water, as well as channels that water would follow if it fell on the surface. Drainage patterns are next in importance after landform, and they provide information about soil permeability, soil texture, cohesiveness, areal homogeneity, ease of erosion, ground slope, relative depth of soil mantle, presence of and type of rock, and dip of beds. With experience, one can make a judgment from these patterns as to probable general composition. As water flows

⁵Judy Ehlen. 1981. *The Identification of Rock Types in an Arid Region by Air Photo Patterns*. U.S. Army Engineer Topographic Laboratories, Ft. Belvoir, Virginia, ETL-0261, AD-A109 144.

over a surface, it can scour out ever-deepening and ever-lengthening channels whose shape, intricacies, and arrangement form patterns that are directly related to the materials containing them. These patterns are evaluated in two ways. The first is an analysis, in terms of pattern type and density, of the surficial arrangement of the drainage net as one would see it looking down on it. This is called the Drainage-Plan. The second is an analysis of the cross sectional shapes and gradients of the channels that carry water to the collectors. This is called the Drainage-Elevation.

Plan. Aside from forms of control such as caused by bedding, jointing, and fractures, the drainage pattern and its density are functions of soil permeability, slope, and the climate, especially the amount and distribution of precipitation. Well-defined surface drainage patterns do not develop on pure granular materials, such as sands and gravels, because the water drains downward through the spaces between the granules and downslope until it finds a low, or until it exits from the material. With sufficient water, this mass of material becomes saturated, at which point the water must flow over the surface, and can leave a trace of its passing in the form of an erosional scar, or a series of tone changes. With torrential rains, water can fall on a surface faster than it can drain into the interior, and under such conditions, the water will flow over the surface. Aside from patterns of infiltration basins, drainage patterns do not usually develop on the surfaces of granular deposits. At the edges of a dissected deposit, such as a granular terrace, there will usually be a few gullies, but these will not extend very far into the plain, and they are not branched into ever-smaller tributaries. If the granular material is well graded and contains some small fraction of the fines in its composition, the permeability will be reduced and the gullies will extend farther back.

In materials that are not wholly permeable, such as clays or soils that contain a significant amount of clay and silt, some of the water runs over the surface and scours out a drainage pattern. The less the permeability, the more the surface runoff and the greater will be the erosional scouring and the number of gullies. A relative index of permeability can be obtained for a drainage pattern by expressing the drainage in terms of total length of the combined drainageways in relation to a unit area, e.g. kilometers of drainage per square kilometer of terrain. Lower values of the ratio are associated with the more permeable materials. In making this kind of an evaluation, one should remember that slope differences can cause different drainage densities for materials having the same permeability and also that vegetation can hide drainage channels that would contribute to the overall density, if they could be mapped.

For a soil composed of expansive clay particles and in a dry condition, some initial portion of a rainfall will drain internally through the dessication cracks and voids and not run over the surface. As this water comes in contact with the clay particles, they expand, filling in the cracks and voids, at which point the mass becomes impermeable, and the water must flow over the surface, leaving as a sign of its passage an intensively developed network of drainageways. In general, and for similar slope conditions, the finer the drainage net, i.e. the closer the gullies are spaced, the less the permeability and the finer the texture of the material.

In this part of the stereo photo analysis, all standing water, low spots, and paths that water would follow if it fell on the surface are traced out on the overlay material. It is important to record as much as possible of the fine detail, especially the first-order drainage, i.e. the small unbranched tributaries that terminate at the limits of a watershed. Such detail provides a basis for better identification of drainage basin limits and divides and for developing inferential information as to geological structure and stratigraphy. This overlay can be removed from the photomosaic and placed on a smooth, light-toned background so that the drainage patterns can be examined in isolation. The pattern is evaluated in terms of homogeneity, arrangement, density, and angularity. Wherever any one of these characteristics changes, there is a basis for a boundary that denotes some change in materials or conditions, or both. If, for example, the pattern was uniformly the same throughout the area of study, then one must conclude that surficial materials and conditions, whatever they might be, are also uniform throughout that area. If one can break out three drainage patterns or three variations of a common pattern, then one must assume that the area contains at least three different materials or conditions, or some combination of both. Sometimes it is difficult to locate an exact position for a boundary between two patterns. For example, a drainage pattern might change gradually from one end of the study area to the other, in the sense that at one end the pattern shows fewer contributing gullies to the collectors than at the other end. This could be caused by the fact that the rock, say a sandy, silty shale, contains a gradually lessening amount of sand as one goes across the study area, which would gradually and slightly alter the permeability of the material and the resulting drainage pattern.

Once the boundaries have been established and the various drainage patterns described, the significance of these findings must be determined. There are some relations that apply in general. As stated previously, the denser or more finely divided the drainage net, the more impermeable and fine grained the material. The more angular are the intersections of gullies and channels to their collectors, the harder and more resistant the material. In soft and easily eroded material, such as clay shale, silt deposits, limestone, or soft sandstone, the wanderings and intersections of collectors and gullies are curved and rounded. As the material becomes harder, the intersections become more angular. Sinusoidal roundedness in the drainage plan is indicative of roundedness in the landform profile, and angular paths and intersections are indicative of an angular landform profile.

Several types of drainage patterns, along with the materials and conditions to which they are linked, are listed on the Drainage Factor Pattern Sheet in appendix A. These patterns represent pure, or idealized, forms and although they do occur in the field, they are not found as frequently as are the transitional and combined patterns. The more common patterns of this group are dendritic, parallel, rectangular, trellis, radial, and annular.

The dendritic, or branching tree-like pattern, is probably encountered more frequently than any other. In this pattern there is no indication of control over the direction of flow, other than downhill. The tributaries form acute angles with the main collectors, and the individual streams tend to be curved rather than straight. This pattern develops on materials that have uniform resistance to erosion. As such, it is indicative of homogeneity in composition and structure and is associated with relatively incompetent rock and soil materials. In sedimentary rocks, such a pattern has an added structural connotation in that the units must be horizontal, or nearly so. The significance of this pattern is that it is an indicator of homogeneity in materials and conditions, both areally and vertically, at least to the depth of erosion.

A parallel drainage pattern indicates a single direction of flow. Such patterns are found on soil and rock materials that are uniform in composition and structure and that are on an inclined surface. The tributaries joining the collectors form acute angles that become smaller, or more acute, as the slope increases. Parallel patterns can also be caused by closely spaced parallel fractures in homogeneous rock that is at or near the surface.

A rectangular drainage pattern indicates two directions of flow, or orientation of stream segments, that are about equally developed. Usually the tributaries join their collectors at right angles, and the stream segments tend to be straight rather than curved. This pattern is a result of structural characteristics in the rocks brought about by intersecting sets of fractures or foliations and is indicative of relatively competent material at or near the surface.

A trellis pattern also has a rectangularity established by two directions of stream orientation. In this case, however, the directions are not equally developed, i.e. one direction has more drainage than the other. The tributaries join their collectors at right angles, and stream segments tend to be straight. This pattern develops on structurally altered rocks composed of nonuniform materials at or near the surface. This type of control is most frequently associated with tilted, interbedded, competent and incompetent sedimentary units, and some low grade metamorphic rocks. The longer parallel streams follow the direction of the bedding, i.e. strike, or the principal foliation. In sedimentary sequences, the tributaries on opposite sides of collectors usually show a difference in

length, as well as in the patterns of junctures. Tributary junctures that develop on dip slopes tend to be Y-shaped, and those that develop on scarp slopes tend to be T-shaped. Tributaries that are equal in length on both sides of collectors are suggestive of beds dipping about 45° . T-shaped tributaries on both sides of a divide indicate that the bedding, or foliation, is vertical, or nearly so.

A radial drainage pattern arises when the drainage is directed away from, or towards, a central topographic high or low. On a local basis, the drainage channels can be nearly parallel. Drainage that flows from a central high is called centrifugal and is most frequently associated with volcanic cones and plug-like intrusive rocks. Drainage that flows inward towards a central low is called centripetal and is frequently associated with sedimentary basins.

Annular drainage patterns also show symmetry about a central point, either a topographic high or low, but with two components of direction – radial and concentric. The tributaries follow radial courses and intersect at right angles with the collector streams, which are following concentric courses. This pattern is an indicator of structural domes or basins and can be found in areas of sedimentary and low grade metamorphic rocks, as well as in igneous terrain.

Elevation. This pattern refers to the shapes of the gullies in cross section and in gradient. It is an important pattern element because soil textures and soil profile features can be interpreted directly from a detailed study of gully systems and gully characteristics. Bedrock is continuously being broken down by mechanical means into ever smaller pieces, which accumulate in various parts of the landscape as deposits of particles ranging in size from boulders to pieces visible only with a magnifying lens. There are limits, however, to the particle size that can be produced by grinding, and it is about 0.002 to 0.003 mm (2 to 3 micrometers). These smaller particles are called silt. There is another group of particles that result not from grinding, but from weathering (chemical decomposition) and subsequent recrystallization of the soluble products. These are called the clay particles. Although these plate-like particles have a size distribution that overlaps the silt group, the overwhelming majority of them have sizes less than 0.002 mm. The designation of particle sizes associated with gravel, sand, silt, and clay depends on the soil classification system being used. In *The Unified Soil Classification System*,⁶ the approximate ranges are

⁶Arthur Casagrande. *The Unified Soil Classification System*. Corps of Engineers, U.S. Army, Technical Memorandum No. 3-357, Vols. 1 and 3, March 1953. (The Unified Soils Classification System was developed by Dr. Casagrande and was adopted by the U.S. Army Corps of Engineers in 1942 as the Airfield Classification System. Other agencies also used this system and extended its application to all phases of soil work. In 1952 discussions were held between the Corps of Engineers, the Bureau of Reclamation, and Prof. Casagrande. The result was a modification of the Airfield Classification System and a renaming of it as the Unified Soil Classification System. Several references provide details of this system).

coarse gravel	—	19 to 75 mm (.75 to 3 inches)
fine gravel	—	4.8 to 19 mm (.19 to .75 inch)
coarse sand	—	2 to 4.8 mm (.08 to .19 inch)
medium sand	—	.4 to 2 mm (.02 to .08 inch)
fine sand	—	.07 to .4 mm (.003 to .02 inch)
finer (silts and clays)	—	less than .07 mm (.003 inch)

Note that in the Unified System size distinction is not made between silts and clays. These are differentiated on the basis of their behavior. Refer to appendix D for further details on particle sizes.

Gravel and sand are the coarse-grained parts of the soil, and the distinction between the two on the basis of size is an arbitrary one, for the engineering properties are similar throughout, varying primarily in degree. As sand becomes finer, it acquires some of the characteristics of silt, especially a decreased permeability, and it can be visually indistinguishable from silt. There are also distinctions based on chemical composition and physical properties that are associated with the various groups of particles. Gravels consist of fragments from igneous, metamorphic, and sedimentary rocks. Consequently, they have a varied chemical, or mineral, composition. It is an infrequent event to find gravel deposited without sand. The two are usually together, either intermixed as in a well-graded deposit, or interleaved as lenses and layers of coarse sandy gravel alternating with coarse sand, etc., and frequently with some amount of precipitated material present. Whatever its composition, a deposit is an indicator of the types of rock available to the stream that formed the deposit, an item of information of little concern to the photo analysis, but which can be of use during a ground reconnaissance.

Sand, on the other hand, is most frequently made of quartz (*silicon dioxide*), an abundant substance that is hard, resistant, inactive chemically, and durable through long periods of time. There are other kinds of pure sand, such as gypsum and coral, but these represent but a small fraction of the whole. Coarse sand frequently contains other particles, but as the grain size becomes smaller, the quartz fraction becomes larger. Fine sand is usually pure quartz — the sturdy unweatherable residue of the degradation process. Sand grains can be rounded or irregular as a result of how much abrasion they have received. They are neither cohesive nor plastic, and in bulk, their water-holding capacity is very low. Because of the large sizes of the pore spaces, the passage of water can be rapid. Because of the small sizes and the lack of cohesiveness, sand can be carried by the wind.

Silt and clay are the fine-grained components of a soil and are called the nonplastic fines and the plastic fines, respectively. They are important as a group because they significantly alter the engineering characteristics of soil when present in small amounts. If a granular soil contains as little as 10 percent of fines, it can lose much of its permeability and be subject to frost heaving. As a result, soils that contain any significant amount of silt and clay are sources of engineering problems because they can have pronounced changes in physical properties caused by changes in water content or by being disturbed. When in a dry, powdered state, silt and clay are visually indistinguishable. When chewed, silt has a gritty feel, and clay has a creamy feel. In the presence of water, they have very different properties.

Silt particles, the end result of the grinding process, are irregular in shape, are seldom smooth or flat, and are composed mostly of quartz. They could be accurately described as micro-sand particles. Being composed of quartz, both sand and silt are very inactive in a chemical sense. The silts, however, are so small that they have some different physical properties. The pores between the grains are restricted enough to influence the passage of water, and consequently, these soils are not as permeable as sand. By the same token, they have a higher capillary rise and a higher water retention capability. Because silt particles frequently have an adhering film of clay, the smaller ones can show evidence of cohesion, plasticity, and adsorption. Being small and noncohesive, silt can be transported by the wind as well as by water, and it occurs as aeolian and fluvial deposits, both pure and mixed. Silt is unstable when water is present and can turn "quick" when saturated. It is somewhat impervious, it is difficult to compact, and its properties in place are very different from those of the disturbed soil.

Clay particles are small enough so that surface effects override mass effects, and most of the particles are small enough to have colloidal properties. These particles are flat, have about 10,000 times more surface area than an equivalent weight of medium grade sand, and surface forces can be very strong. Consequently, surface phenomena such as cohesion (particles sticking together) and adsorption of water, chemicals, and gasses are very pronounced in the clays. Because the clays are formed by processes of chemical decomposition and recrystallization, they vary greatly in mineral and chemical composition. Clay is highly plastic when moist, and it forms hard cohesive masses when dry. Clay soils are practically impervious, difficult to drain, difficult to compact if wet, and undergo volume changes as a function of water content.

The patterns of drainage-elevation, i.e. gully cross section and gradient, that develop in a soil are determined by the properties of permeability, cohesiveness, plasticity, compressibility, etc., and these are functions of the amounts of clay, silt, sand, and gravel in the soil, the soil profile development, and the climate. In general, there are three basic gully cross section and gradient combinations that correspond to the three textural groups of granular soils (sands and gravels), silty soils, and clayey soils.

In noncohesive granular materials, the gullies are V-shaped in cross section and have short, steep gradients, i.e. the gullies are slightly longer (4 to 6 times) than the width of the gully at the top of the V. With more of the fines present, the gullies become longer. In well-graded deposits that have been dissected, such as river terraces, the exposed walls can be vertical.

In silty soils the gully cross section has a flat bottom and steep-to-vertical sides. The gullies can be relatively long and have a gentle gradient throughout, except where it steepens at the headwall. The manner in which the silt was deposited (aeolian or fluvial) also influences the shape. Flat-bottomed gullies with vertical walls can be formed in any noncohesive deposit as a result of subsurface drainage or ground water sapping. Conditions necessary for this can occur in saturated alluvial deposits as a result of an increase in ground water levels or of excessive rainfall. Vertical walls can also be caused by undercutting, as in a river cutting into a loessal bank, i.e. a bank of wind-deposited silt. In fluvial deposits of silt, the gullies have this boxy shape, which could be the result, in part at least, of subsurface flow undercutting at the base with a subsequent slumping. In aeolian deposits, the gully walls are steep, but not vertical. Based upon our field measurements, the walls are most frequently between 55° and 60°.

Nongranular, cohesive, and plastic soils, i.e. the clays and silty clays, develop a gully with a saucer-shaped cross section and a long gentle gradient. In a relatively pure clay soil, the saucer-shaped cross section is very broad, shallow, and gently rounded.

Additional information about drainage patterns in relation to rock type can be found in appendix G and in ETL Report 0261.⁷

EROSION. Landform, drainage, and erosion are interrelated. Without erosion, drainage patterns and, consequently, landforms could not evolve. There are several forms of erosion, however, and each leaves a pattern that can provide information about the composition of materials, conditions, and climate. The term "erosion" is used here to refer to the overall procedure of breaking down earth surface materials, i.e. soils and rocks, and of moving the pieces from one place to another. In keeping with most usage, weathering as a destructive process is included as a form of erosion even though it does not involve transport of the altered material. Processes that are responsible for loosening, breaking, or dissolving earth surface materials include

Mechanical

- running water
- rainfall
- waves
 - impact
 - compression of air
- moving ice
- corrasion
- expansion in confined spaces
 - freezing of water
 - crystallization

Chemical

- dissolution (limestone, gypsum, etc.)
- weathering

Thermal

- thawing (thermokarst, and the active zone in regions of permafrost)
- temperature changes (differential coefficients of expansion for different crystals)

The forces that are responsible for moving the altered or loosened material are running water (including currents), wind, ice, and gravity. The mechanical destruction of the land, with removal of the pieces by running water, is the most common of the erosive processes, and because of the importance of its patterns, it is discussed and evaluated under the heading of drainage. Each erosional process has associated with it patterns of shape, tone, and texture. Because of these patterns, one can identify the types of erosive mechanisms and, therefore, infer something as to the composition and properties of the material. In this part of the analysis, one looks for indicators of the mechanisms of erosion, describes them, and evaluates their significance. For example, occurrences of blowouts on a surface are suggestive of the presence of a sandy material; the presence of sinkholes, a form of chemical erosion, is indicative of limestone; the presence of depressed center polygons in permafrost regions (freeze-thaw) is indicative of a silt/ice mixture and the possibility of large amounts of subsurface ground ice.

DEPOSITION. Material that is eroded away must be deposited elsewhere, and the resulting patterns are controlled by the nature of the material, conditions, and climate. The regional desposits that form sedimentary rocks are not considered as part of this pattern group. Some depositional formations are large enough to be classified as landform patterns, e.g. large deltas, fans, terraces, dunes, volcanic cones, etc. Even so, their patterns are indicative of composition.

This part of the analysis serves as a checkpoint to review the imagery for indicators of deposition and to evaluate their significance. Some of these patterns are associated with relatively small features, e.g. examining gully mouths to see if fans are present, which, if found, would indicate that there is a source of granular material upstream. Most depositional patterns are caused by mechanisms involving water, wind, ice, gravity, biological material, and man.

The patterns of water-deposited materials that are of interest in this part of the analysis are those forms of depositions brought about by moving water, i.e. rivers and streams, flood (including the sheet variety), currents, and waves. These deposits are mostly materials in the forms of stream terraces, fans, deltas, beaches, beach ridges, bars, eskers, kames, outwash, etc. This deliberately ignores the subaqueous deposits that form in seas, estuaries, lakes, and ponds and which are still submerged. The nature of a deposit in terms of composition is a function of the source of the material and of the speed and depth of the moving water. Consequently, these deposits contain materials that range from silt-sized particles to boulders, show some degree of sorting, and frequently show some degree of stratification. As an example, fans show a lateral sorting, with the coarse fraction at the gully mouth and the finer fraction at the leading edge. The cross section profile of a fan is also related to particle size distribution. The higher the arch of a fan as compared to its width, the coarser is the composition.

Compared to water-associated deposits, wind-deposited material has a more restricted grain size distribution, usually silt and sand-size particles. Most aeolian deposits form features that are large enough to be evaluated as landforms, e.g. dunes, loessal ridges, loessal plains, etc. In general, aeolian deposits show streamlining, smoothly arced edges, interconnected shapes, fluting; and they tend to look "windswept." Shape can provide information about composition. In sand dunes, the shape is related to wind speed and its constancy in direction. Long lineal dunes, i.e. tens of kilometers in length, are shaped by very strong winds with a constancy of direction. Of the dune formations, they are likely to have the most coarse particle-size distribution. Moderate winds are associated with barchane dunes and weak winds with transverse dunes. The latter type usually has a finer soil texture. Irregularly shaped dunes or star-shaped dunes result from changing wind directions.

Deposits associated with ice are complex masses of material that are sometimes difficult to classify because there are many overlapping types, and the precise mode of formation is frequently uncertain. Many of these deposits are poorly sorted and sometimes stratified. Those that are caused by running water (glacial melt) have been mentioned, i.e. eskers, kames, and outwash. Deposits that are formed by action of the ice, in contrast with action of the meltwater, include moraines, drumlins, and till. Moraines can be formed in different ways. A terminal, or end, moraine is formed by the edge of an advancing glacier shoving surface material ahead of it into long, curved, ridge-like features that outline the shape of the advancing sheet of ice. This material is frequently composed of till, but can consist of the resident soil and rocks of a previously unglaciated area. Consequently, this type of moraine can vary greatly in composition, although it is usually unsorted and unstratified. Lateral moraines form at the sides of a glacier as a result of the moving ice plucking and scraping material from the valley walls and distributing it along the edge. Material can also be deposited by melting the ice of a stagnant glacier out from under material suspended in a shear plane or resting on the surface as a perched moraine. Morainal forms are not as well sorted as the water deposited features, and contain more of a nongranular fraction. Drumlins are long, rounded, low-lying hills shaped by the action of the glacier on the till at the ice-ground interface. Ice that melts in cyclic freeze-thaw sequences can also move material, as well as provide some degree of sorting. It is this mechanism that brings large rocks to the surface in a poorly sorted soil, produces frost boils, and contributes to the slow downhill movement of the surficial material in periglacial areas, i.e. solifluction.

Although gravity is the ultimate cause of all deposits, airborne or waterborne, its use here is restricted to those materials that have slid or fallen directly onto their resting places, i.e. water and wind were not involved in the transport. The pattern elements of interest here are associated mostly with talus, avalanches, slides, slumps, etc.

The common biological deposits are peat and muck, which are derived from the accumulation of vegetation in low-lying areas such as ponds, bogs, swamps, estuaries, etc. In an aerial photograph, these are seen as dark or black flat surfaces surrounded by higher ground. Although they have a high economic value, they are problem areas for engineering construction.

Man-induced deposits most frequently occur in the forms of tailings piles and ponds associated with mining and ore production, ridge-like mounds and hills from strip mining and quarry operations, and landfill (dredge or hauling).

VEGETATION. As to which photo pattern is next in importance is a moot point. At present we give the edge to vegetation for two reasons. First, vegetation information is important to many different tasks. As an example, the results from an analysis of vegetation patterns can be used to provide information about the vegetation itself in terms of type, spacing, density, canopy closure, stem diameter, vigor, etc.; or to provide information that is directly or indirectly linked to other characteristics such as climate, soil texture, soil or rock type, depth of soil mantle, presence of ground water, potability, etc. Second, and perhaps more important, vegetation patterns have not been exploited to their full potential. Based on the accumulated evidence, one can only conclude that the limit to the indicative uses of vegetation patterns is our lack of knowledge. Consequently, research efforts in this field of study should receive more emphasis. Although much is known, in a general sense, about vegetation and environmental characteristics, very little is known about the details of the intricate network of relations between vegetation type, state and vigor, climate, landform, soil texture, moisture, ground water, chemical composition (of plants and soils), and associated spectral reflectance, fluorescence, and radiometric properties. Once established, these relations might provide usable indicators as to soil composition, soil conditions, mantle depth, water sources, water potability, mineralization, and salinity, let alone provide an improved vegetation mapping capability. As to how much proves to be reliable and useful, only the results from research can tell.

Air photo scales suitable for engineering soils evaluation and environmental data base preparation, i.e. in the 1:20,000 scale range, are too small for use in species identification. Vegetation types or large pure stands can, however, be identified and boundaries established between groups. These boundaries are frequently associated with changes in soil texture, soil moisture, topography, landform, and orientation, and they give supportive information to factor boundaries established in earlier phases of the analysis. Arid regions research done by ETL has established some usable relations between landform, soil texture, and vegetation community.⁸ Although these results must be tested in other regions, there is no doubt that knowledge of either landform or soil texture within an area can set the basis for a fairly accurate prediction of the vegetation communities, and vice versa. Also, vegetation patterns can provide information about climate. A closed canopy forest requires over 76 cm (about 30 inches) of rain per year. Some species in certain locations require much more than that. Progressively less rain means progressively less tree cover and more shrubs and grasses. A continuous grass cover requires at least 25 cm (10 inches) of rain per year, with some grasses needing double that amount. When the annual amount of precipitation falls below 25 cm, the grass cover breaks into clumps, specialized species appear, and the vegetation becomes more widely separated.

⁸Melvin B. Satterwhite and Judy Ehlen. 1980. *Vegetation and Terrain Relationships in South-Central New Mexico and Western Texas*. U.S. Army Engineer Topographic Laboratories, Ft. Belvoir, Virginia, ETL-0245, AD-A095 159.

The procedure for classifying the vegetation during an image analysis is a function of the nature of the project, and schemes are frequently tailor-made to fit project goals. As will be discussed in the section on data base preparation, the analysis can be simple or complex as a function of the classification scheme used. At present no existing system combines simplicity, photo-based origin, Army needs, and the capability to incorporate other data sources. Such a system is being developed at ETL (refer to appendix E).

CULTURAL. The analysis of cultural patterns can be done for at least three reasons: (1) to derive information about the culture itself, (2) to use the cultural patterns to derive information about other terrain factors, and (3) to use the cultural patterns directly in terms of some military problems. As an example of the first, the economic characteristics of a given society can be deduced by an analysis of the cultural patterns. As an example of the second, a pattern of cultivated fields, such as the alternating tones of fallow farming, can provide clues as to soil texture and the general climate, or the presence of a quarry can support predictions of rock type. As an example of the third, the knowledge of the location of above-ground structures provides information with reference to the military problems of cover and concealment and cross-country mobility. Because cultural information is needed for so many different uses, it has not been possible to provide a single satisfactory classification scheme, let alone a scheme based on the analysis of photo patterns.

From the military point of view, terrain information needs are better expressed as a land cover/land use map, which is a combination of the patterns of culture, vegetation, and surficial geology. Of the classification schemes presently available, none of them adequately meets Army requirements, and none of them is well suited to the use of remote sensing techniques. The classification scheme should be as simple as possible, at least through the first level, and perhaps into the second; and it should provide a basis for incorporating into the higher levels, technical details from the literature or ground surveys. Within ETL, over 20 classification schemes have been evaluated, and one was tested by photo analysis. No one system lent itself readily to the use of remote sensing imagery, and neither did any one system adequately address Army needs. ETL is trying to develop a land cover/land use classification that will meet these goals. A review of this effort is in appendix F.

PHOTO TONES AND TEXTURE. Photo tone and texture are descriptive terms that do not lend themselves to precise definitions. Nevertheless, these patterns can provide information about specific materials or conditions, as well as information to support conclusions developed during the analyses of other factors. When used with respect to black and white photography, photo tones refer to the gray levels in the image. If used with respect to color photography, photo tones refer to the color. When the colors are other than the neutral ones (white, grays, black), they are difficult to describe.

In the case of panchromatic photography, the photo tones represent the brightness of an object as averaged over a very broad spectral bandpass. Evaluating a tone is relative, is frequently done within a frame of photography, and is expressed in such terms as light, dark, lighter than, darker than, redder than, uniform, speckled, etc. Although photo tones can be measured and expressed in terms associated with optical density and Munsell notation, etc., no practical use is gained by such procedures because, for most terrain surfaces, photo tones do not have an absolute relation to anything. Frequently there is some range of tones associated with some range of conditions, but it is not absolute in the sense that if A, then always B, or if the optical density is 0.21, then the surface is granite, or if it has a particular Munsell notation, then it is a wheat field.

The tones in an aerial photograph are the end product of a number of interactive items and events. Included in these are the molecular nature of the surface material; the quality of the light (sunlight, skylight, time of day, season, atmospheric properties); slope and orientation of the surface; angular relations between the surface, the camera, and the sun; off-axis variation in exposure (this can be equivalent to over one-half an f-stop from principal point to edge of format when using a wide angle lens); presence of surficial structure; local meteorological conditions (dry, wet); spectral transmission characteristics of lenses and filters; and characteristics of the emulsion and of the processing method. For high altitude or satellite systems with long focal length lenses or with small scan angles, which are recording at near constant or similar sun times, the variations caused by some of these relations are reduced. For conventional aerial photography, however, the changes can be significant. For example, because of off-axis falloff of exposure, a material can have different gray tones or different colors as a function of whether it is directly beneath the camera or off to one edge of the format. A wide angle lens increases this effect.

The term "wide angle" refers to a lens whose focal length is less than the maximum dimension of the format. A normal lens is one whose focal length is approximately equal to the maximum dimension of the format, and a telephoto is a lens whose focal length exceeds the maximum dimension of the format. As used here, the term "format" refers to the image size recorded by the camera, e.g. 35 mm, 4 by 5 inches, 9 by 9 inches (aerial camera), etc. In the case of the 35 mm camera, the diagonal of the rectangular image formed on the film is about 50 mm, and for that camera, a 50 mm lens

is the normal lens. For a 9- by 9-inch aerial camera, the diagonal of the square image recorded on the film is about 12.7 inches, and a 12-inch focal length lens is considered to be normal. A 6-inch focal length lens is frequently used with a 9- by 9-inch aerial camera, and for this camera, that is a wide-angle lens. Consequently, there is considerable falloff of exposure at the edges and corners of the picture.

Tone variations can also occur as a result of changes in the angle between the sun, the features on the ground, and the camera. For example, considering only sunlight and neglecting skylight, an area on the ground that is towards the sun from the camera station can add a specularly reflected component of sunlight and show as a light tone in the positive image. When this same area is away from the sun, with reference to the camera station, then its image cannot receive a specular contribution and is formed only from backscattered sunlight, which results in a darker tone in the positive image. Surface roughness also influences the directional scattering of incoming light. Frequently occurring surficial variations in relief that are equal to, or greater than, the wavelength of the incoming radiation will cause the light to be scattered in different directions. The light that is of concern to photography has wavelengths that are less than 1 micrometer. Consequently, most surfaces are rough and scatter light in all directions, sometimes more in one direction than another. As a result of these effects, two materials can have a high contrast at the trailing edge of the format, with A being dark gray and B being light gray, and they can show a reversal of this contrast when the same materials occur near the leading edge of the format. The boundary of a tone pattern can also have a shape that can be frequently related to other events and conditions.

Texture refers to the visual impression of surface structure, and in some instances it is difficult to describe texture separate from tone. Descriptive terms include smooth, coarse, silky, mottled, speckled, banded, etc. For example, an area containing a dense stand of pine trees will have a different texture than a mixed hardwood stand, and a plantation of pine trees with its 2-dimensional arrangement of rows has a very different texture than a natural pine forest. Large areas of sedimentary rocks exposed across the beds can present a striated appearance, and when closely spaced these striations can give a grain-like appearance to the terrain similar to wood grain. Some examples and further discussion of tone and texture patterns as used in the context here can be found in other publications.^{9,10}

The Council for British Archaeology, 7 Marylebone Road, London NW1 5HA. CBA Research Report No. 12. Derry and Sons, Ltd., Nottingham, England.

In most cases, these patterns are associated with areas of relatively bare or exposed soil and rock or with an area of uniform vegetation cover. Although photo tones and texture are important sources of information, care must be taken in evaluating them, especially those of soils because climate and season greatly influence the development and the detectivity of these patterns. With respect to soils, tones and textural patterns can provide information about identity, origin, uniformity, horizon development, moisture relations, etc. As an example, in panchromatic photography, silt has a bright uniform photo tone and a silky texture. Soils of the Wisconsin glacial till show an intricate mottling of light and dark gray tones that are related to soil texture and moisture conditions, and soils of the Illinoian glacial till develop white fringes around gullies, which are indicative of a profile development, i.e. a gradual alteration of the soil into layers of different composition. Curvilinear tone streaks on low flat areas are suggestive of fluvial deposition. A rectangular light-toned network in flat farmland is indicative of the presence of drainage tiles, which in turn suggests a high water table and waterlogged soils. With respect to exposed rocks, tone and texture can provide supportive information as to type. For example, in igneous rocks, the mafic group, which includes basalt and gabbro, has dark photo tones; and silicic rocks, such as granite, tend to have lighter tones. For further information on tone and texture characteristics of some rock types, refer to appendix G. With respect to vegetation, tone and texture can provide information about composition or vegetation type.

SPECIAL. This category includes items that do not easily fit under other factor headings, or items that although discussed under other factors, are sufficiently direct indicators of identities and conditions that they warrant additional evaluation. This part of the analysis serves as one more checkpoint to examine the imagery for clues to support previous findings or to suggest new relations or identities. These patterns frequently depend on some inherent quality of the material or on some inherent nature of an action. Typical patterns include joints, faults, soil slumps, mudflows, tears, and some patterns of drainage, erosion, and tones. As an example, windblown silt deposits have an internal vertical structure that accounts for several patterns that serve as direct indicators of the presence of such a material. These include the pinnate drainage pattern, flat-bottomed steep-sided gullies, terracettes and pinnacles on gully walls, and vertical-faced road cuts. The pinnate, gully cross section, and road-cut patterns would be evaluated under their respective sections, i.e. drainage and cultural. The terracettes and pinnacles, too small to be considered as landforms, would probably be discussed under this section. Another example, slumps and tears in an otherwise smooth valley wall would be indicative of instability and potential engineering problems.

Within this category, an important member is that collection of pattern elements called lineations, including curvilinear. They are called lineations because they are seen in the imagery as lines of various lengths and distinctness crossing the landscape. One group of lineations is associated with fractures in the rocks, i.e. joints and faults. The term "fault" indicates a perceptible displacement between the sides of a fracture along the fracture plane. In length, these features range from small cracks barely discernible with a handlens to transcontinental lineations. These fractures are a record of the rock's response to stress applied through a variety of forces, such as tension, compression, torsion, thrust, shearing, mass expansion, mass shrinkage, etc. The causative agents include movement of molten rock that can result in a surface upwelling, i.e. a dome; the folding, twisting, bending, and stretching of rock as a result of plate movements; the expansion of a previously compressed mass; or the volume changes as a result of cooling from a liquid phase to a solid phase. Another form of lineations can be seen in the exposed beds of tilted sedimentary rocks. In these instances, the lines mark the contact between beds of different composition. Lineations are usually visible in the imagery as a series of aligned discontinuous tone changes, such as light streaks in the soil caused by better drainage over a fracture, dark streaks where water has been blocked and the soil is moist, lines of taller vegetation due to more available moisture, segments of drainage channels, escarpments, etc.

The patterns of lineations are important for several reasons. In an evaluation of an area from an engineering or construction standpoint, a rock that has a pattern of closely spaced intersecting fractures would certainly be suspect as a zone of weakness and potential instability. In limestones, the fracture pattern, in conjunction with the drainage and overall structure, can be indicative of possible subsurface voids. Fractures also serve as conduits to recharge the ground water table. The path to the water table can be short and direct or a very long, slowly descending lateral one. Consequently, the fracture pattern, in conjunction with geological structure and soil and rock composition, is important to the task of searching an area for a possible source of water. Being conduits, the fractures can convey unwanted material into a water table. Thus, they must be evaluated when searching for a site for waste disposal, either surface or deep-seated.

This summarizes the important characteristics of the factor patterns associated with this manual procedure of photo analysis. As results from in-house research and the scientific literature accumulate, some of these sections will be rewritten and illustrated. Without doubt, new pattern relations will emerge, and equally without doubt, some of our current concepts will need modification. In some of the factor groups a classification of the pattern elements would be of use, and in some instances such an effort has been started. In other instances, there is a hodgepodge of information to be sorted, evaluated, and tested before a semblance of a classification scheme can emerge or a decision made to abandon the effort. This is particularly true for the photo tone and texture group of patterns. In any event, these are the patterns that carry information about the terrain and on which an analysis is based. The following section discusses some of the problems associated with getting the information from the photos, classifying it, and converting it into some form of data base.

FEATURE EXTRACTION AND DATA BASE PREPARATION

J. N. Rinker and P. A. Corl

The manual procedure of image analysis, particularly of stereo aerial photography, provides a versatile and rapid means for obtaining reliable information about the terrain in terms of its origin, composition, properties, climate, and probable response to stress. The results of a photo analysis can be expressed as an environmental data base, i.e. a collection of photomosaics and factor overlays, which, in turn, can be interpreted with respect to a specific problem. Consequently, this procedure has direct application to many general problems, as well as to specific tasks. Examples of these include

1. General worldwide problems associated with
 - a. Identifying and mapping geological structure, rocks, soils, vegetation, or land cover/land use
 - b. Engineering site selection and evaluation
 - c. Location of engineering materials
 - d. Land use planning
 - e. Probable location of minerals
 - f. Probable location of ground water
 - g. Waste disposal
 - h. Environmental data base preparation
 - i. Environmental impact prediction
2. Specific military problems such as
 - a. Cross-country movement
 - b. Cover and concealment
 - c. Analysis of an area of operations
 - d. Data base development for MGI, DLMS, TTPDB, etc.

The first step in obtaining information for a data base by image analysis is to extract information from the imagery. A general understanding of how this is done provides insight into both manual and machine procedures, as well as into the nature and level of competence required in a manual analysis and in data base preparation.

Regardless of the pattern elements involved, or the goal of an analysis, there are but three ways of obtaining information from imagery. They are direct observation (d), measurement (m), and inference (i). Direct observation denotes the act of seeing or detecting a feature or pattern element directly in the image. Examples include detecting, marking, tracing, or bounding roads, structures, airports, bridges, rivers, ponds,

wooded areas, hills, drainage nets, landform units, etc. In general, it is easier, in the sense of requiring less skill, to detect cultural objects than natural features. There are exceptions to this, of course, because some cultural features, such as isolated towers, can be difficult to find, and some natural features, such as rivers, ponds, isolated volcanic cones, etc., are readily detected by direct observation. Natural features such as landform, drainage net, and gully cross section require more skill and experience in order to observe their shapes accurately. Some of the direct observation tasks can be done by machine or can be greatly assisted by machine procedures, particularly for features with well-defined shapes and sharp boundaries or with well-defined spectral characteristics.

Measurement refers to the use of devices to determine distance, length, width, height, slope, area, volume, tree density, direction, etc. There are also measurements such as optical density and the handling of density changes by fourier transforms. These, however, are not considered in this discussion. Again, different levels of skill and training are required for different types of measurements. For example, measuring height and slope is more difficult than measuring width and length.

Inference refers to inductive and deductive reasoning and judgment to derive or predict information not directly apparent in the image. Examples of the type of information produced by this procedure include predicting physical properties and conditions, probable composition and classification (rocks, soils, vegetation, etc.), and response to stress, etc. This procedure requires higher levels of skill, experience, and knowledge than the others. Although obviously based on direct observation and supplemented at times by measurements, the inferential procedure contains the added task of determining the significance of that which is seen. It is the assembled statements of significance that guide the reasoning towards an understanding of and conclusions about the landscape in terms of its properties, conditions, probable composition, and response to stress. Shape, arrangement, tone, and texture can be seen directly, significance cannot. It must be deduced. Consequently, inferential procedures require levels of knowledge, experience, and skill beyond those needed for direct observation and measurement. Fortunately, inferential procedures are not required for many data base information needs. Table 1 lists some of the associations that exist between the basic methods of extracting information and the types of information.

There is an added complication in evaluating skills and associated tasks because direct observation and inference can overlap when one considers the relations between detection, identification, and classification. At times, these three steps are combined into one operation using a single skill level and a single extraction method. At other times, these tasks are distinctly separated with each based on a different method of extracting information and a different level of skill. In general, as an object or a pattern becomes either less distinct or more complex, the steps of detection, identification,

and classification become more separated and require more skill and experience. For example, on large-scale stereo aerial photography, an analyst could detect, by direct observation, an isolated object, identify it as a tree, and classify it as a pine tree, all in one glance. When working with complex patterns, less distinct imagery, smaller scale imagery, or cluttered background patterns, these steps become separated. To continue with the tree as an example, the analyst would first detect an object. Because of its general shape, height, and location, it is identified as a tree. A further evaluation of shape, tree shadow, and tone in relation to that of other trees might lead the analyst to the inference that it is a conifer, possibly a pine tree. A definite separation of steps has occurred.

Cultural patterns also suffer these complications. If a bridge is off center in the format so that there is some obliquity in the stereo view and if the scale is suitable, the analyst could detect, identify, and classify the bridge in one glance. If that same structure, however, is aligned along the flight line and the road and bridge surface have the same brightness, then it is possible that the bridge will not show in the image, that is, it cannot be detected by direct observation. Therefore, its presence is inferred simply because the road crosses a water body. In this instance, the classification cannot be done from the photos.

The goal of the classification also influences the relations between detection, identification, and classification. A simple land cover/land use classification can be done by lower skilled analysts using mostly direct observations, some measurements, and little if any inferential information. In this case, the steps of detection, identification, and classification will be near simultaneous for most units. If the requirements call for a detailed classification of some aspect of the terrain, then the analysis becomes complicated, requires higher levels of knowledge and experience, and is based mostly on inferences drawn from an evaluation of all the pattern elements, as well as a consideration of the climatic regime in which they occur. For these applications, the steps of detection, identification, and classification will be widely separated in both complexity and time requirements.

In some instances, the classification step will be difficult, in others it cannot be completed, and in others the steps of detection and identification might not exist. For example, assume that an analyst has detected a pattern and identified it as a group of buildings among other buildings. The structures are directly noted and duly marked. The next level of classification could be in terms of building type, building height, building use, or building composition. Which of these is chosen depends on the purpose of the analysis. An economic data base would have the classification in terms of use. A military data base might require all four. Building type can be obtained from the photos by direct observation and by using photo keys. Building height can be estimated or

measured. In most cases, building use must be determined inferentially or from other information. With few exceptions, information about building composition must come from other sources. In this example, assume that the analyst wants to identify the building in terms of its use. This identification rests on an evaluation of the relations of the specific structure or group of structures to the surrounding patterns. These include location of the site in relation to the terrain and to other buildings and their types, as well as the absence or presence of transportation, parking, loading docks, etc. From these considerations, the analyst might decide that the buildings are used for commercial/retail operations. Detection and identification took place with ease and near simultaneity; whereas, classification was complicated and time consuming. There are instances, of course, that although the buildings have been detected and identified, the use cannot be determined. For instance, a group of two-story row houses built as single family residences could now contain small retail operations, government offices, and a religious group, without a consequent change in photo pattern.

An example that has the steps of detection and identification missing can be found in the task of trying to get soils information in an area that has a dense, continuous cover of vegetation. Because of the vegetation cover, the soil and rock surfaces cannot be seen. Consequently, the determination of soil properties, i.e. its classification, is the only step involved, and it will be a complex one relying on inferences derived from an evaluation of other pattern elements. In any event, whether dealing with natural features or cultural features, the road from detection, through identification, to classification can be short, long and tortuous, or dead ended.

The human factors of interest and enthusiasm have such a strong bearing on the quality and quantity of work produced by an individual that it is difficult to state absolute training and educational requirements or to assign absolute levels of skill to any given task. Nevertheless, some general statements can be made as to the types of expertise associated with different analysis efforts. For simplicity, three levels of training and experience are presented, essentially the extremes and a midpoint (table 2). A number of typical analysis tasks are listed in table 3. For each task, the associated methods of extracting the information and the level of skill needed to do it are indicated. Note that the task of classification is listed three times and that each entry requires a different level of competency. This supports the earlier statements indicating that classifying pattern elements is a troublesome issue, simple in concept, but not necessarily simple in practice. Nevertheless, it is an issue that is always present because basic to the development of any data base is the fact that some sort of classification scheme is needed in order to express the information. Each pattern element, or group of pattern elements, must be assigned a name or symbol that is indicative of the characteristics of that pattern

element and its relation to other members within its group. These classifications can be based on different principles and can be expressed in different terminology. In a very real sense, it is the classification requirements that determine both the complexity of the analysis and the level of skill needed to do it. For example, one could classify the land cover of an area on the basis of very broad categories, such as vegetation cover, no vegetation cover, water bodies, structures, roads, and railroads. Although simple, the classification does provide information and requires only a minimum of skill. A more informative classification would be vegetation (forest, brush, grassland, mixed), cultural (structures, roads, railroads, bridges, cultivated land), and barren (rock, soil, water). Obviously, this would be a more complete analysis and would require higher levels of skill and experience. Classification can also be based on specific type, use of the land, properties of its components, or origin to name a few alternatives. For example, a soil map could show a first level of classification based on origin because that information is an early step in the logic of predicting soil composition and texture. In table 4 some examples of classification schemes are listed, the types of analysis tasks needed to do them (direct, measurement, inference), and the associated levels of skill required.

The information presented in tables 1 through 4 is of an obvious general nature and, as such, is suggestive rather than absolute. Even so, the tables do show that much practical information that is of direct use to both Army and civilian needs can be obtained by the lower level of the skill groups. Table 5 lists categories that such a group should be able to map, trace, or otherwise identify on stereo aerial photography in the scale range of 1:20,000 to 1:100,000. Although these categories form a relatively simple land cover/land use data base, they provide information directly linked to perhaps half or more of stated specific needs, as well as to general problems such as cross-country movement, evaluation of areas of operation, a first cut at cover and concealment, etc. With a slightly increased skill level, and photo pattern sheets, additional classifications could be made as to canopy closure, road type, general structure type, etc. If classification requirements go much beyond this, then more than a slight increase in skill is needed. Classifying the patterns on the basis of soil composition, surficial geology, or vegetation composition, etc., requires a greater outlay in time, effort, and knowledge. If this increased level of information is worth the extra expense is a moot point. In some cases yes, but in the majority of cases, the answer might well be no. There is a universal and continual need for reliable general information. There is not an equivalent need for specific information. However important that need is when it does exist, it is neither universal in time nor location. A reliable general information data base can usually be augmented as need arises. The routine requirement for levels of, or types of, information above that needed and using a poorly designed classification system can result in getting little, if any, information and in creating a situation that seems hopelessly complex.

During an analysis, a variety of photo-derived information is produced in the form of overlays, sketches, and notes. Some of this information can be portrayed on overlay material in place on the photomosaic by tracing out the factor in question, e.g. the drainage net or the road net. These overlays are referred to as direct factor overlays, and some of them can be prepared by the lower skill level groups. Other elements of information cannot be drawn in place on the overlay and exist as separate sketches and notes. These elements include terrain profiles, gully cross section and gradient, and some measurements. By evaluating the direct factor overlays, sketches, notes, and measurements, other types of information are deduced that can also be expressed on a map-like overlay keyed to the photomosaic. These overlays are referred to as derived factor overlays. For the most part, these involve some form of classification, and consequently, their preparation requires using individuals from the higher skill levels. Table 6 lists the various information groups and data base elements that are routinely obtained from an air photo analysis. Furthermore, these elements and information groups are representative of many of the MGI needs of the Army. At present, machine and machine-assisted techniques seem to be of little consequence in generating any of the material that goes into the overlay, either direct or derived. Even so, they are of consequence in storing, filing, and presenting such information. Attempts to apply machine techniques to data production are being made in several places. Exactly where and how they will be used and the levels of efficiency, practicality, and reliability they can achieve remain to be learned.

TABLE 1. Basic methods for extracting information from imagery by manual procedures

METHOD	SYMBOL	PROCEDURE	COMMENTS
Direct	d	Direct observation or detection of objects, shapes, patterns, arrangement, tone and texture, etc. Identification of simple pattern elements.	In general these methods require less training, experience, and judgment. Of direct help here are photo keys, Air Photo Indicator Sheets, Feature Identification Sheets, and machine assisted techniques of analysis and measurement.
Measurement	m	Determination of dimensions (width, length, height), volume, area, slope, tree density, direction, etc.	
Inferential	i	Inductive and deductive reasoning from associated clues and convergent lines of evidence to derive information not directly apparent in the imagery.	This method requires more ability, training, experience, and knowledge. Of assistance here are P.I. Logic Sheets, Air Photo Pattern Summaries, Air Photo Indicator Sheets. Logic software plus an example data base in an interactive system could also be of assistance.
For each factor, information element, or classification unit, some or all of the following characteristics are wanted.			
DETECTION (d)			
IDENTIFICATION/CLASSIFICATION (d, m, i) Type, species, road/bridge class, etc.			
DESCRIPTION (d, m, i) Shape (plan and elevation), arrangement, orientation, extent, depth, dimensions, slope, gradient, structure, areal and vertical homogeneity, boundary specification, color, tone, texture, etc.			
CONDITIONS (d, i) Status, wet-dry, frozen, unfrozen, seasonality, growth stage, active, abandoned, under construction			
PROPERTIES (i, m) Hardness, porosity, permeability, erodibility, density, spacing, etc.			
SUPPLEMENTAL FEATURES (d, m, i)* Bedding, joint/fractures, faults, strike, dip, slips, sinks, voids, bars, cones, polygons, burns, actual use, etc.			
DYNAMICS (i) Historical development, environmental interaction, mechanisms of change, effect of weather, etc.			
		SIGNIFICANCE (i) Suggests materials, composition, bearing load, etc.	
		SIGNIFICANCE (i) Suggests materials, conditions, nature of the climate, classification, use, etc.	
		SIGNIFICANCE (i) Suggests materials, climate, development, classification, presence of instability, limits of use, potential for change, etc.	
		SIGNIFICANCE (i) Suggests materials, conditions, limits of use, classification, potential for change, etc.	
		SIGNIFICANCE (i) Suggests properties, conditions, materials, development, subsurface characteristics, instability, limits of use, etc.	
		SIGNIFICANCE (i) Suggests development, climate, limits of use, potential for change, response to stress (natural and cultural), etc.	

*Denotes that the d and m procedures require a higher level of skill than normal.

TABLE 2. General Training and Experience Associated with Three Levels of Skill that Represent the Extremes and the Midpoint ¹

- 1 Minimum level of training – High school diploma, 4 weeks of specialized training, plus 4 weeks of on-the-job training for each specialty, and 12 weeks experience.

- 2 In addition to the above, this level requires 1 or 2 years of experience and considerable knowledge (college level) about at least one specialty, such as soils, geology, vegetation, land-form, drainage, land cover classification, some land use classification, bridges and road classifications, etc.

- 3 This level requires an unusual depth of knowledge (graduate level) about a specialty as well as a working knowledge of several disciplines, plus considerable working experience.

¹Based on material in:

J.N. Rinker, J. Ehlen, A.E. Krusinger, T.R. Currin, A.O. Poulin, P.B. McCracken. 1976. *Capabilities of Remote Sensors to Determine Environmental Information for Combat*. U.S. Army Engineer Topographic Laboratories, Ft. Belvoir, Virginia, ETL-0081, AD-A035 139.

TABLE 3. A list of common photo analysis tasks and associated methods of information extraction and skill levels. The methods for extracting information are defined in table 1. Skill levels are described in table 3. Note that the first five tasks contain a large amount of the basic information needs and that they can be done by the lowest skill level group.

Task to be Done	Methods for Extracting Information	Skill Level
1. Detection/Identification – Simple. Mark, bound, and trace simple objects and pattern elements, e.g. roads, railroads, water bodies, structures, towns, airports, forest, cropland, barren, some landforms, some drainage patterns (subhumid and arid regions), etc.	d	1
2. Classification of some elements such as roads, bridges, etc., and simple land cover/land use.	d, m	1
3. Measurement – Plan. Dimensions, direction, orientation, etc.	d, m	1
4. Description – Simple. Layout, arrangement, orientation, and shape.	d, m	1
5. Measurement – Elevation. Heights, slopes, and measure or estimate areas and volumes.	d, m	1–2
6. Detection/Identification – Complex. Mark, bound, and trace complex objects and pattern elements, e.g. landform, drainage, profiles, cultural, vegetation.	d, m, i	2
7. Classification of land cover/land use patterns, vegetation patterns, cultural patterns, surficial materials.	d, m, i	2
8. Description – Complex. Shape, slope, structure, symmetry, areal and vertical homogeneity, etc.	d, m	2
9. Interpretation of data as applied to specific problems and prediction of simple forms of environmental impact.	d, m, i	2
10. Detection/Identification – Supplemental Features. Mark, trace, or indicate supplemental features such as bedding, joints/fractures, strike and dip, slips, tears, flows, etc.	d, m, i	2–3
11. Prediction of properties and conditions. Examples include resistance to erosion, hardness, stem spacing, stem diameter, presence of subsurface voids, and unstable materials and conditions.	d, m, i	2–3

TABLE 3. (Continued)

Task to be Done	Methods for Extracting Information	Skill Level
12. Significance of information elements, singly and collectively.	i	2-3
13. Classification of rocks, soils, and complex versions of landform, vegetation, land cover/land use, etc.	d, m, i	2-3
14. Preparation of environmental data base.	d, m, i	3
15. Interpretation of an environmental data base for construction site selection and evaluation, environmental impact, and prediction of responses to stress.	i	3

TABLE 4. Classification plans, methods of information extraction, and needed skill levels. None of the categories in any of the columns can be rigorously separated from the others. There is a transition. In general, however, the classification schemes that are needed for the preparation of any given data base determine the complexity of the photo analysis and the levels of skill and experience needed to complete the task.

Types of Identification and Classification	Example	Methods for Extracting Information	Skill Level
Generic	forest, tree, shrub, grassland, cultivated land, road, bridge, hill, bare soil, etc.	d	1
Specific	rain forest, oak tree, closed evergreen, broadleaf shrubland, cereal grain crop, interstate, truss bridge, barchane hill, windblown silt	d, m, i	2
Composition	mixed hardwood forest, cement concrete road, wooden bridge, sand hill	i	2
Use	Recreational forest, rangeland, cropland, railroad bridge, quarry, etc.	d, i	1-2
Property	closed canopy forest, thorny shrubland, impermeable soil, 30% slope, average stem spacing, etc.	d, m, i	2-3
Conditions	Gypsy moth infested forest, diseased crops, saturated soil, unstable slopes, potable water, etc.	d, i	2-3
Origin	residual soils, transported soils (aeolian, glacial, fluvial, etc.)	i	2-3

TABLE 5. Land cover and land use categories that should be identifiable by skill level 1 individuals, i.e. the lower of the three skill levels. This is based on using stereo aerial photography within the 1:20,000 to 1:100,000 scale range. Although these items form a simple land cover/land use data base, such information is directly applicable to many stated needs. If supplied with suitable Air Photo Indicator Sheets, this same group should be able to classify within some of these categories, e.g. amount of canopy closure, road type, bridge type, crop type, dam type or purpose, structure type and probable use, landform type, etc.

- Trees
- Brush
- Grassland
- Mixed
- Cropland
- Barren
- Water bodies
- Drainage-plan
- Roads
- Railroads
- Airports
- Bridges
- Dams
- Rights of way
 - Power lines
 - Pipelines
- Fence lines, hedgerows
- Structures
- Collections of structures (strip, town, etc.)
- Mixes of trees and structures
- Some landform and slope classes

TABLE 6. Data base information obtainable from air photos. Some of the direct observation type of information abstracted from the photos can be portrayed in the form of tracing, or other notation, directly on transparent material covering the photos. These are Direct Factor Overlays. Other types of information, i.e. observations and measurements, are recorded as notes and sketches. Information that is derived by inference and judgment can also be presented on overlays keyed to the air photos. These are Derived Factor Overlays, and usually consist of classification terms assigned to bounded areas and special identifications. These overlays, notes, and sketches form an environmental data base that can be evaluated with respect to a given problem or task.

AIR PHOTO PATTERN ELEMENTS

Landform
Drainage-Plan
Drainage-Elevation
Indicators of erosion
Indicators of deposition
Vegetation
Cultural
Tone and texture
Special

OBSERVATIONS, SKETCHES, AND NOTES

Information obtained by direct observation but which cannot be mapped or traced in place on the photos

1. Landform: profiles, shape characteristics, cross sections
2. Drainage-Elevation: gully cross section and gradient
3. Indicators of erosion
4. Indicators of deposition
5. Tone and texture

EXAMPLES OF INFORMATION THAT CAN BE MEASURED, OR APPROXIMATED

1. Dimensions of objects
2. Radius of curvature
3. Areas and volumes
4. Tree height and density
5. Canopy closure
6. Stream width
7. Slope
8. Spacing and orientation

DIRECT FACTOR OVERLAYS

Patterns and features traced or marked in place by direct observation

1. Drainage-Plan
2. Ridgelines
3. Lineations
4. Dip and strike
5. Pattern boundaries
 - landform
 - drainage
 - vegetation units
 - vegetation damage
 - land cover
 - land use
 - flood damage
 - structures
 - tone and texture
6. Cultural objects: roads, railroads, trails, canals, airports, pipelines, power lines, towers, buildings, bridges, some property boundaries
7. Special features: locations of slumps, tears, gradient changes, cross section changes

DERIVED FACTOR OVERLAYS

Examples of classifications and predictions based on inference and evaluation of the stereo photos, Direct Factor Overlays, sketches, and descriptive material

1. Geology: rock type, distribution, structure, properties, cross sections
2. Soils: type, distribution, depth, properties, conditions
3. Vegetation: type, distribution, properties (closure, spacing, diameter, vigor)
4. Slope classes
5. Land cover/land use identities
6. Critical areas: sites of potentially unstable soils, rocks, slopes, etc.
7. Probable locations of subsurface voids, ground water, minerals, contamination points, etc.
8. Change (needs sequential imagery): land use, population, economics, landform, etc.

PRODUCTS AND IMAGE ANALYSIS DOCUMENTATION

J. N. Rinker and P.A. Corl

If this manual procedure of analysis is to be improved, be more routinely applied, be involved in technology transfer, or be a guide to help develop computer-assisted techniques, it is a prerequisite that its logic and information elements be tested, certified, and documented in a readily usable and reliable manner.

There are but two sources of information for such documentation. One is the review, evaluation, and acceptance or rejection of existing information, including our own reservoir of knowledge, experience, field data, and imagery. The other is the discovery, testing, and establishing of new information. At ETL, the Center for Remote Sensing (CRS) is actively working on both aspects, i.e. the evaluation and refinement of existing knowledge, and the search for and development of new knowledge. Aside from the technical papers in the open literature, much of the CRS documentation is being put into formats designed to present and relate small single elements of information. In the case of manual image analysis (photo, radar, LANDSAT), the information unit is a pattern element that has proven to be an indicator of some aspect of the terrain. In the case of LANDSAT digital analysis, our information elements to date are spectral reflectance measurements and band intensity measurements associated with certain materials and conditions, or combinations of materials. The spectral reflectance measurements include information about pure materials, i.e. a material uniformly filling a field of view, as well as combined responses, such as varying ratios of vegetation and soils within a field of view. In the case of infrared thermal radiation, the information units contain specifications of time, bandpass, and meteorological conditions associated with feature/background contrast ratios. At present, the air photo pattern elements are receiving more attention than are the others. Each element, regardless of source, must be tested. Is it false, or is it true? If true, is it always true, or true only under certain conditions, and if so, what are the conditions? In order to answer these questions, it is necessary to consider ground observations, and measurements, as well as the pattern elements in the aerial photography or other imagery. Only by such a procedure of image analysis, field checking, arguing, and technical critique can one separate opinion from fact, establish validity, and set the basis for subsequently putting the material into a printed form.

Of the elements from the literature that have gone through the test and critique cycle, many have fallen by the wayside because they were proven to be either inaccurate or of too limited an application. Many others, including our own, have needed extensive modification. Very few have made it through to the final product without alteration. Of necessity, a large amount of printed material has been, and is being, collected and reviewed. This includes Army manuals, the open literature, internal reports, data bases, classification schemes, etc. Many of these items had what proved to be a surficial plausibility that read well, but which fell apart upon testing and critical review. Additional

complications included inconsistencies within the internal logic, contradictions within and between documents, and a noticeable lack of clarity. As a final test, one must be able to sit down with the images and the associated document, do what is said, see what is claimed can be seen, deduce what is claimed to be possible, and then go to the field and find that the results are correct. If this cannot be done, then that element or procedure must either be modified to make it true, or discarded. Before progress can be made in all of the ramifications associated with the applications of air photo and image analysis and their potential transition into a machine-assisted procedure, the bits and pieces, and the logic that binds them together, must be documented, and it is equally important that the documentation be correct.

In addition to conventional research reports, the information about patterns, materials, conditions, procedures, and radiometric characteristics is being expressed in a series of related documents that can be expanded or otherwise modified in the future. As field work, laboratory work, and literature review progress, deletions, alterations, and additions will be made. At present the proposed series consists of

Summary Sheets

Factor

Materials

Air Photo Patterns

Air Photo Indicator Sheets

Photo Interpretation Logic Sheets

Spectrophotometric Data Sheets

Radiance Data Sheets

Classification Schemes

Soils

Vegetation

Land Cover/Land Use

Application Summaries

Ground Water

Minerals

Soils Mapping

In general, the items in the top group are in formats that, in addition to other uses, can provide a means for selecting and transferring information into programs associated with machine-assisted or interactive procedures, such as a knowledge-based expert system, or into programs associated with digital feature extraction. Items in the middle

group are associated with data base preparation. Items in the lower group are meant to outline sequences of pattern elements associated with a given task. Those products in the upper group entitled "Materials, Air Photo Patterns, Air Photo Indicator Sheets, and Photo Interpretation Logic Sheets" are part of the documentation for the manual procedure of air photo analysis. In addition, they serve to evaluate the applicability of machine processes and to supply information in a form that can be incorporated into knowledge-based expert systems.

These documents supplement each other and, as a set, are designed to portray and illustrate the reasoning processes that an expert in air photo analysis would follow in making decisions and predictions about the nature of the terrain in terms of its identities, composition, conditions, practical utilization, and response to stress or cultural impact. This information can then be codified into rules and some form of logic network based on sequential questions and answers. With the rules and the yes/no answers, the non-expert can be led through the reasoning steps by a sequence of "If yes, then . . ." type of statement that leads to some conclusion. At any point, the user should be able to query the system as to the why of the statement.

It was mentioned earlier that the state of the art for obtaining detailed terrain information was the manual procedure of air photo analysis. This will continue to be true, even if one assumes the existence of a perfectly designed interactive system. In order to make use of the stored rules so that predictions can be made, a series of direct questions must be answered, and the answers to these questions come from the photos. For such questions as "Is the gully bottom flat?" (yes or no), "Is the gully gradient uniform?" (yes or no), "Do the walls of the gully have uniform slopes?" (yes or no), etc., the answers can come only from an analysis of the stereo photo, and this is a manual procedure, except for those features that can be identified by automatic machine recognition techniques. Nevertheless, an interactive system can direct the analyst to consider pattern elements that might have been overlooked and into paths of reasoning that were missed and, of more importance, to enable the nonexpert to produce results similar to those of an expert analyst. There is, however, this basic division of labor: the analysis of the photos is manual, and the interpretation of these results is by the computer. An example of a question and answer sequence of a type associated with knowledge-based systems is in appendix I.

SUMMARY SHEETS

Factor Summary Sheets. These are single sheet descriptions of each of the pattern element groups of landform, drainage-plan, drainage-elevation, erosion, deposition, vegetation, cultural, photo tones and texture, and special. Where appropriate, a first-order classification is, or will be, included. These represent a first draft, and changes will be made as work and discussion continue. Insofar as earth surface materials are concerned, the more important members of this group are landform, drainage (plan and elevation), erosion, deposition, and tone and texture. These groups are easier to organize and illustrate than are the other pattern elements. In any event, it may turn out that this sort of information is better presented in text form rather than as a series of summary statements. If so, these sheets will be dropped. The Factor Summary Sheets completed to date are in appendix A.

Materials Summary Sheets. These are single sheet descriptions of general characteristics and properties of earth materials. Because the physical and chemical properties of any material set the bases for the kinds of patterns that erosion and weathering can develop in that material, an understanding of these properties is of help in making judgments about patterns, pattern variations, and significance. The list of materials that will be treated in this section includes members of the igneous, metamorphic, and sedimentary rocks, and some soils. Examples of sheets completed to date are in appendix A.

Air Photo Patterns Summary Sheets. These single sheet summaries serve as reference guides to the photo pattern elements associated with a given material, in a given condition, and in a given climate. Each sheet is for a specific material and climate relation. As an example, one sheet is entitled "limestone, flat-lying, humid and subhumid areas." Each summary describes the characteristic landforms one can expect to find, the patterns associated with drainage (plan and elevation), the indicators of erosion that one should look for, depositional patterns that can form, vegetation associated with the material, typical cultural patterns that can occur, the nature of the tones and textural patterns, and special pattern elements that are uniquely related to the subject. These sheets provide basic relations that can be codified into rules for an interactive system. The materials to be described in this manner include members of the igneous and metamorphic rocks; the sedimentary rocks in the forms of massive pure beds, thin beds, and interbedded units; and some soils and surficial deposits. Air Photo Indicator Sheets will be used to illustrate the pattern elements that are discussed. Examples of these sheets are in appendix A.

AIR PHOTO INDICATOR SHEETS

These single sheet guides illustrate and describe specific pattern elements that are related to or indicative of a given material or condition. The pattern elements to be presented are those within the factors of landform, drainage (plan and elevation), erosion, deposition, vegetation, cultural, tones and texture, and special. Each sheet contains an air photo example, stereo if needed, plus ground photography when available. Along with each indicator are given the condition or the material that it indicates, the geographic location, the climatic zone (based on Trewartha, 1957), comments about the pattern, how the relation was verified, sensors that can detect the pattern, limitations in terms of film/filters, season, etc., and the engineering significance where appropriate. The pattern elements listed in the Air Photo Patterns Summary Sheets as well as the dominant and supportive indicators in the Photo Interpretation Logic Sheets will be illustrated with this form of indicator. Because these sheets illustrate the basis for making a judgment, or a decision about a pattern element and its relations to terrain components, they form a portion of the knowledge-base part of an interactive system. Specifically, they are meant to illustrate questions in the analytical sequence (refer to appendix I). These sheets can also serve as general reference material, as image keys, and as training aids. Indicator Sheets completed to date are in appendix B. Whether or not a similar approach will be taken with other forms of imagery remains to be determined.

PHOTO INTERPRETATION LOGIC SHEETS

The original purpose of these sheets was to provide a means for evaluating the manual procedure of photo analysis and determine what steps, if any, lent themselves to machine procedures, interactive systems, etc. Although the sheets do serve this purpose, they have been arranged to meet other goals as well. They provide a sequential listing of the pattern elements used in photo analysis. Next to each element are listed the dominant and supportive pattern indicators that the "expert" uses to identify or gain information about the specific element. Each of these pattern indicators is judged in terms of stereoscopic aerial photography, monoscopic aerial photography, automatic pattern recognition, and interactive systems. Adjacent to these evaluation columns is a column for comments. As many as possible of the dominant and supportive pattern indicators will be cross referenced to appropriate Air Photo Indicator Sheets. The pattern elements listed are from the factor groups of landform, drainage (plan and elevation), erosion, etc. At present, work will be restricted to landform and drainage (plan and elevation). When these are completed to some acceptable level and if it is still the intent to continue, then attention will be turned to erosion, deposition, and tone and texture. At this point, the evaluation columns for manual and machine procedures will be eliminated to provide space for additional comments and for cross-referencing the pattern indicators into appropriate data bases, e.g. MGI, Digital Land Mass System (DLMS), Tactical Terrain Products Data Base (TTPDB), etc. These sheets, along with the Air

Photo Indicator Sheets, provide the data units and basic elements of logic for incorporation into an interactive system. Specifically, they are the source of the questions that guide the analysis (refer to appendix I). Examples of the Photo Interpretation Logic Sheets are in appendix C.

SPECTROPHOTOMETRIC DATA SHEETS

Although there are several uses for these sheets, including camouflage and signature studies, they are oriented towards feature extraction based on supervised digital classification of LANDSAT scenes. An absolute spectral reflectance curve also enables one to estimate emissivities and thereby predict spectral emittance. Many materials have reflectance curves that are identical over some portion of the electromagnetic spectrum, but which differ in other parts. In this instance, one sensor would depict them as the same and another sensor would note a difference. The use of various film/filter combinations and multiband sensors to separate different materials is based on these relations.

The LANDSAT Multispectral Scanner (MSS) is perhaps the best known and most frequently used of the multiband techniques. It collects reflected sunlight from each instantaneous field of view (IFOV), which is about 70 by 70 m, and records the intensities in each of four spectral bands. The bands, which for LANDSAT 1 through 3 are numbered 4, 5, 6, and 7, have the respective wavelength passes of 0.5–0.6 μm (green), 0.6–0.7 μm (red), 0.7–0.8 μm (infrared), and 0.8–1.1 μm (infrared). On LANDSAT D, the new Thematic Mapper on board provides six more bandpasses. The approximate wavelength ranges are 0.45–0.52 μm , 0.52–0.60 μm , 0.63–0.69 μm , 1.55–1.75 μm , 2.08–2.35 μm , and 10.4–12.5 μm . The latter bandpass is commonly used in infrared thermal techniques. If one considers satellite systems other than LANDSAT,¹¹ then a variety of reflectance and emittance data are becoming available throughout the visible, photo infrared, thermal infrared, and microwave regions of the spectrum. Aside from conventional manual analysis of the imagery, such data can be manipulated by digital techniques, and a variety of programs have been developed for this purpose, most notably for the LANDSAT MSS.

Successes in digital classification, or at least in digital discrimination, are most frequently associated with features that have strong and unique spectral differences from their surroundings. Such features include damaged vegetation, vegetation units, exposed zones of alteration in soils and rocks, lakes, sediment loads, snowfields, etc. Discrimination and identification are, of course, two different things and the latter is the more difficult task. Even for discrimination, however, a program developed for one scene will not necessarily work on another scene of the same area or for the same type of terrain

¹¹NOSS National Oceanic Satellite Systems, 23 March 1979. A joint effort by National Aeronautics and Space Administration, Department of Commerce (National Oceanic and Atmospheric Administration), and Department of Defense (Navy, Air Force, and Army).

components in a different area. Nevertheless, a supervised classification, i.e. a classification procedure wherein the analyst is directly involved and can correct or eliminate obvious misclassifications and otherwise modify selection rules, is increasingly being used. Although a nonsupervised, or automatic, classification might work for a few features, such is not yet applicable for deriving general terrain information. There are several problems associated with classifying digital spectral information, including (1) variations in the quality and quantity of incoming sunlight as a result of atmospheric changes and seasonal changes, (2) variations in surface orientation, (3) lack of baseline spectral reflectance measurements, and (4) the IFOV being frequently composed of different surfaces.

Because of the obvious importance of spectral relations to many scientific needs, as well as the continual improvement of airborne and satellite systems to record spectral intensities in narrower and more numerous bandpasses, the abilities to discriminate and, in some cases, to identify, will be improved. Consequently, there will be an increasing use of digital analysis and digital classification techniques. Because in such procedures detection and identification are based on differences in spectral characteristics, it is important to establish the relations between cause and effect, determine the variances within scenes, and gain an understanding of the practical limits of reliability. Towards these ends, we are collecting from soils and plants a variety of laboratory and field spectral measurements (reflectance, fluorescence, absorptance) as functions of age, moisture, salinity, mineral content, stress, illumination characteristics, season, and percent cover in an IFOV. With reference to reflectance studies, the experiments include spectral, diffuse, and total hemispheric measurements, with the latter being done by means of integrating spheres. In some cases, the vegetation and soil samples are chemically analyzed to find out if there are any relations between the spectral reflectance, vegetation composition, and soil composition. Results of this research have been presented in the open literature, as well as via internal reports.^{12,13,14,15} A single sheet format is being developed at ETL to display this type of information on a feature-by-feature basis. In addition to the spectral data, regression equations will be included where appropriate. Such a data sheet might help in making decisions about LANDSAT band choice and band ratioing for digital classification, as well as provide information for photographic detection. A sample sheet is in appendix H.

RADIANCE DATA SHEETS

Infrared Thermal. Research at the CRS-instrumented test site at ETL has generated a large amount of data associated with infrared thermal techniques, and some of these results have been released in the form of scientific reports.^{16,17,18,19} Single sheet summaries can be prepared that show radiation characteristics of various features/background combinations. Such sheets could include radiation variances as a function of time, meteorological conditions, physical conditions (material type, temperature, moisture, etc.), time of maximum contrast between feature and background, etc.

Microwave (Active and Passive). Cooperative research efforts with the Naval Research Laboratory (NRL), U.S. Geological Survey (USGS), U.S. Fish and Wildlife Service (USFWS), and National Aeronautics and Space Administration (NASA) include evaluating passive microwave radiometers, a microwave imager, and radar with reference to vegetation type, canopy closure, soil, canopy contribution, canopy masking of ground radiation, and canopy obscuration of the terrain to radar. As these flights are infrequent, the data accumulate slowly. Variations in the recordings from the passive systems have shown some correlation with vegetation patterns, but whether these are due to differences in vegetation radiation properties, changes in soil type, or soil moisture is not yet known. Chemical analysis of the vegetation, especially for metallic elements, will be done to find out if there are any relations between such data and microwave emittance and reflectance. The research into the spectrophotometric, radiometric, and chemical characteristics of vegetation, soils, and rocks helps to develop knowledge applicable to specific feature extraction and to data base preparation in general. Figure 1 shows the ways in which this type of research supports the overall problem of data base generation and feature extraction. At present, we do not know if the results of these studies will lend themselves to summary sheet presentation.

CLASSIFICATION SCHEMES

Whenever a large assortment of information elements is to be presented in a data base, some sort of classification system is needed to relate the pieces to each other and to establish a hierarchy. By and large, classification systems that are usable with photo analysis and that are directed towards, or at least include, information elements related to Army needs are not readily available. Consequently, effort has gone into developing classification systems for soils mapping, land cover/land use, and vegetation.

With reference to soils mapping, existing classification systems are based on laboratory or field measurements, not on photo patterns. Within ETL, a scheme has been developed that is based on the manual procedure of photo analysis and that has been critiqued but not tested. With reference to land cover/land use, 20 classification systems were evaluated, one of which was tested by photo analysis. None of the systems were satisfactory, either in being usable with imagery or in supplying sufficient amounts of terrain information needed by the Army. In view of the fact that the systems were designed around economic considerations, the latter finding is not surprising. Within ETL, work is continuing on developing a system that meets three goals: first, it must be applicable to manual techniques of image analysis, at least at the first level; second, it must be able to assimilate other sources of information at higher levels of classification without the need of altering the basic structure; and, third, it must include Army information needs. A similar situation exists with reference to the vegetation classification and a scheme has been developed that is based, in part, on work in ETL Report 0058, "Study of Classification and Nomenclature of Vegetation." This scheme has been critiqued, partially tested, and is being modified.

There are some characteristics that all classification schemes should share. A report by Liu lists qualifications that a soil classification system should have.²⁰ Because these comments apply equally to other subjects, they are paraphrased below.

1. Use of distinct attributes, but as few as possible, as the basis for forming groups.
2. Develop a logical, simple, and concise scheme that is easily remembered.

²⁰T.K. Liu. 1970. "A Review of Engineering Soil Classification Systems." In: *Special Procedures for Testing Soil and Rock for Engineering Purposes*. ASTM Special Technical Publication 479. Am. Soc. for Testing and Materials, 1916 Race St., Philadelphia, Pennsylvania 19103.

3. Groups should have meaning, i.e. the grouping of the elements should provide an indication of the general broad properties or behavior of the members.
4. Terminology should consist of descriptive, easily understood, and commonly used terms.
5. Symbols cannot properly substitute for descriptive names, but when they must be used they should have specific meaning and be easily associated with the element in question, i.e. avoid codes that have meaning only to a specialist or that require constant reference to tables for translation.
6. Flexibility. The scheme should be capable of adsorbing additions, deletions, or the creation of subdivisions without affecting the basic structure.
7. At least in the early levels of classification, the system should be capable of being used by relatively unskilled personnel.

To these qualifications we have added the following:

1. The scheme must lend itself to photo analysis techniques.
2. It must be able to absorb information from other sources.
3. It must include information elements required by the Army.

Summaries of the work on classification systems for soils, vegetation, and land cover/land use are in appendixes D, E, and F.

APPLICATION SUMMARIES

These are to be basic outlines that show the sequence of steps and the important pattern elements associated with an image analysis directed towards a specific task, such as finding the most probable areas for locating minerals, ground water, or sub-surface voids, etc. Accompanied by indicator sheets, they could be of use with an interactive system. There are interactive programs that are analogous in concept, ranging from early ones in chemistry and diagnostic medicine up to more recent ones in exploration geology. This is a low priority item, and furthermore work cannot start on it until more of the photo analysis documentation is done.

In figures 2 and 3, the relations among the topics that have been discussed are summarized. Figure 2 shows the general relations between the research work and the forms of documentation with respect to an analytical procedure, i.e. based on inductive and deductive reasoning. Figure 3 shows the relations of the various types of documentation and their intended uses with respect to manual analysis, supervised digital classification, and knowledge-based systems for interactive procedures of analysis.

FIGURE 2. Relations between background knowledge, research, and documentation in the development of analytical procedures based on deductive and inductive reasoning.

FIGURE 3. Documentation Uses. Documentation forms associated with pattern analysis are listed at the upper left and those associated with spectroradiometric measurements and radiation characteristics (infrared and microwave) are listed at the upper right. Both types of documentation can be used to support specific projects, as shown in the lower part of the figure, or contribute a knowledge-based system that can be used for interactive analysis and subsequent data base preparation.

LANDFORM

Landform refers to the shape, size, and orientation of any given surface feature and its location within and its relation to the surrounding area. It is the most important pattern element because it is so closely associated with the origin of the material and the subsequent erosional history. An understanding of landforms and their origin makes it possible to bound areas of similar materials and predict their composition, textures, and physical characteristics. In this part of the photo analysis, areas are outlined in which the terrain elements within are uniform in shape, size, spacing, arrangement, and orientation. An area might contain but one item or one shape, for example a plain, or it might contain a collection of shapes, such as a group of similar hills. Each bounded area must be described in terms of shape, size, spacing, arrangement (vertical and horizontal), symmetry and asymmetry, dip, slope, angularity, roundedness, and ratio of top area to basal area (for hills). These pattern element items are indicative of materials and conditions, and they must be evaluated in terms of significance. For example, sharp angularity in the hills, or mountains, is descriptive of the shape. The significance of this pattern is that it suggests the presence of a hard resistant material. Conversely, where hills have soft, gently rounded shapes, it is indicative of a soft material. Climate modifies these aspects and must be taken into consideration. A clay shale can have gently rounded slopes in a moist temperate region, and rugged precipitous slopes in an arid region subjected to seasonal rains and flash flooding. Profiles should be drawn along several transects through the stereo field of view. Upon completion of the analysis the profiles can be converted into predicted cross sections. Classification decisions frequently depend on the purpose of the analysis, scale of the photography, and a definition of the minimum area to be mapped. The complexities of landform classification found in most texts are beyond the needs of air photo analysis; however complicated the shape, it can be assigned into one of four general categories.

Plains. Any relatively flat surface of sufficient extent to be a mappable unit at the scale of imagery used. This includes surfaces that are flat over large regions, such as the Great Plains; surfaces of valley floors, old lake bottoms, terraces, benches, large fans, etc.; and perched flat surfaces such as mesas or buttes. The significance of this shape is that it suggests sedimentation or deposition. Usually, this is indicative of clays, silts, sands, and gravels, either in the form of sedimentary rocks or as soils. Lava flows can form layered sequences, the surfaces of which are flat over extensive areas. These would be mapped as plains. Other pattern elements, however, would direct the chain of reasoning away from considering the material to be sedimentary. The surface of a plain can have variations in relief that lead to such descriptions as: a gently rolling plain, a pitted plain, a dissected plain, etc.

Hills and Mountains. Shapes that have significant positive relief within the area of study, i.e. variations beyond the range of the adjectives used to describe modifications of a plain. Such topography can result from dissection of a plain, doming, or local uplift caused by the intrusion of igneous material, volcanic activity, aeolian deposits, or uplift and folding of the crust. The patterns of hill shape, in plan and elevation, are indicative of the nature of the materials in terms of igneous, metamorphic, and sedimentary rocks and in terms of structure such as dipping, flat-lying, etc.

Basins. Shapes that have significant negative relief and size within the study area, i.e. a depression of some sort. These include old marine and lake beds, large river valleys, solution valleys and depressions, subsidence depressions, etc.

Escarpment. A significant and obvious boundary that separates landform units. When present it is most often as a steep and abrupt change in relief that is continuous over some distance.

SUMMARY SHEET

FACTOR PATTERNS

DRAINAGE - PLAN

Drainage refers to the paths that water follows as it flows over a surface. It is next in importance after landform and provides information about general soil permeability, ground slope, relative depth of the soil mantle, presence of and type of rock, and dip of beds. Aside from forms of control such as caused by bedding, jointing, and fractures, drainage is a function of soil permeability and slope. Surface drainage patterns do not develop on highly permeable materials such as sand. In materials that are not permeable, such as plastic clays and silty clays, the water runs over the surface and develops an erosional scour or drainage pattern. In general, the finer or denser the drainage net the less the permeability and the finer the material. Parvis (1947) identified six basic patterns, dendritic, trellis, annular, parallel, radial, and rectangular. In addition, there are a few patterns that are uniquely related to a given material or to a given set of conditions. These are anastomotic (Zernitz, 1932), pinnate, discontinuous, and braided. There are many variations of the six basic types and it is seldom that one finds the ideal situation where a pure type forms the pattern.

NONE: The absence of a drainage pattern, or erosional scour, indicates that the material is permeable. Water falling on the surface drains down into the interior, rather than flowing over the surface. Such permeability is characteristic of granular materials.	
DENDRITIC: This tree-like pattern indicates homogeneity in composition and conditions and is frequently found on soils of very low permeability, large intrusive igneous masses, and flat-lying sedimentary rocks (sandstone, shales). A drainage pattern can be dendritic on a regional basis and exhibit other patterns at specific sites.	
TRELLIS: This pattern indicates bedrock control of drainage and is characteristic of strongly folded or dipping sedimentary rocks where the edges of the beds have been exposed at the surface, as the leaves of a book. The longer channels result from the erosion of weaker beds along the contact with a more resistant bed. Such channels follow the strike of the beds. The short channels are caused by erosion down the exposed surfaces of the beds.	
ANNULAR: This is a variation of the trellis pattern and is associated with maturely dissected domes. The arcuate paths result from erosion of a weak bed along the contact with a more resistant one.	
PARALLEL: This pattern indicates that the surface, though relatively flat, has a gentle but uniform slope in a given direction. This pattern can occur on the side slopes of valleys and alluvial fans, as well as on extensive areas of a plain underlain by slightly dipping sedimentary rocks.	

RADIAL: This pattern is associated with a central high (hill, dome, volcano), or a central low or basin. In the case of a central high, the water flows from the center outward and is called centrifugal drainage. In the case of a low, the water flows inward toward a central area and is called centripetal drainage. Depending on the size of the dome or basin and the photo scale or area covered, a segment of the radial pattern could be classified as parallel.	
RECTANGULAR: The angularity of this pattern is caused by joints and fractures within the rock or by changes in materials for flat-lying rocks.	
ANASTOMOTIC: This pattern of tortuous windings, interlocking channels, and ox bow lakes is characteristic of flood plains and deltas. It is indicative of a soil of smaller particle sizes than those associated with braided drainage.	
PINNATE: This feather-like pattern, with the relatively close spaced, uniform short gullies feeding into the tributaries is indicative of loessal material, that is, windblown silt. The regional pattern of the tributaries can be dendritic, parallel (as in this illustration), or even show evidence of bedrock control.	
DISCONTINUOUS: This pattern of isolated channel segments and small depressions is usually associated with limestone beds. Discontinuous or interrupted drainage can occur also in thermokarst areas and in permafrost areas.	
BRAIDED: This pattern results from the deposition of coarse-grained material (mostly sand and gravel) in the channels of a heavily loaded stream where stream speed suddenly decreases. As any one channel is filled, new channels develop. Such patterns occur on alluvial fans, desert washes, deltas, and outwash plains of receding glaciers.	

The dendritic, parallel, rectangular, trellis, annular, and radial patterns are from Parvis, M., 1948, *Regional Drainage Patterns in Indiana*, reprint No. 35, Engineering Experiment Station, Purdue University, Lafayette, Indiana. They can also be found in Frost, R.E., 1950, *Evaluation of Soil and Permafrost Conditions*, Vol. I, p.46c, Engineering Experiment Station, Purdue University, West Lafayette, Indiana. These, plus the pinnate pattern, are based on a thesis by Merle Parvis entitled *Regional Drainage Patterns*, 1947, School of Civil Engineering, Purdue University, West Lafayette, Indiana. The anastomotic pattern is based on Zernitz, E.R., 1932, *Drainage Patterns and Their Significance*. Jr. Geology 40(6):498-521.

USAETL-CRS

DRAINAGE-ELEVATION

This pattern refers to the shapes of the gullies in cross section and in gradient. It is an important pattern element because soil textures and profile features can be interpreted directly from a detailed study of gully systems and gully characteristics. These features are closely associated with specific soil types and are not duplicated in unlike soils. For example, gullies with a nonuniform cross section and an interrupted gradient are indicative of changes in materials, e.g. stratified soil conditions, or a soil having a developed profile consisting of contrasting horizons. In general there are three basic gully cross section shapes that correspond to the three major textural groups of granular soils, silty soils, and clayey soils. In granular soils, erosion will develop gullies with a sharp V-shaped cross section and with a short, steep gradient. In silts, the gully cross sections tend to be V-shaped with flat bottoms or box-shaped with flat bottoms. Loessal materials, i.e. the windblown silts, develop very steep gully walls, but they are not usually vertical unless undercut by running water or cut in place during road construction. These soils are removed by headward erosion through flat-bottomed gullies of low gradient. Water-deposited silts tend to develop vertical box-shaped gullies. Although marine sand-clays of the eastern U.S. coastal plain also develop a box-like gully, other pattern elements can be used to separate and identify these materials. Nongranular, cohesive, and plastic soils, i.e. the clays, develop a gully whose cross section has a broad, softly rounded saucer shape and whose gradient is gentle and extends well back into the upland.

V-shaped gullies. These gullies are usually short and stubby with a short, steep gradient. In general, the coarser the material, the shorter and steeper the gully. Alluvial fans are frequently found at gully mouths.

Granular and semigranular, nonplastic, noncohesive soils, i.e. sands, gravels, and combinations.

Flat-bottomed V-shaped gullies with a long gentle gradient ending in a steep face. Alluvial fans are not formed at the gully mouths.

These are indicators of loessal material (i.e. very fine sand and silt).

Box-shaped gullies with vertical sides, flat bottoms, and long gentle gradients.

These are indicators of water-deposited silts and sand/clay mixtures of the coastal plains, as well as indicators of subsurface drainage or ground water sapping.

Saucer-shaped gullies with gentle side slopes and broad cross sections. The gully gradient is gentle, and gullies extend for great distances, gradually feathering out to become indistinguishable.

Nongranular, cohesive, and plastic soils, e.g. clay, silty clay.

SUMMARY SHEET

FACTOR PATTERNS

EROSION

The patterns of erosion provide information about the nature of the material, conditions, and climate. Each mechanism of erosion leaves a telltale pattern of shape or tone. In this part of the analysis one looks for indicators of the mechanism of erosion, describes them, and assesses their significance. For example, the occurrence of blowouts on a surface is suggestive of the presence of a granular or sandy material; the presence of sinkholes, a form of chemical erosion, is suggestive of limestone; the intensity of water erosional patterns suggests something about the nature of the resistance of the material to erosion. In general, these patterns are related to

- Water
- Wind
- Gravity
- Ice
- Chemical
- Thermal
- Man-Induced

USAETL-CRS

PREVIOUS PAGE
IS BLANK

DEPOSITION

Material that is eroded away must be deposited elsewhere, and the resulting patterns are controlled by the nature of the material, conditions, and climate. Some depositional formations are so large that they can be classified as landform patterns, e.g. large deltas, fans, terraces, dunes, etc. Even so, their patterns are indicative of composition.

This part of the analysis serves as a checkpoint to review the imagery for indicators of deposition and assess their significance, e.g. examining gully mouths to see if fans are present, which, if found, would indicate that there must be a source of granular material someplace. In general, depositional patterns are caused by the following mechanisms:

Water (terraces, fans, braided channels, deltas, tone streaks, etc.)

Wind (dunes, sheet cover)

Gravity (talus)

Ice (glacial till, eskers, moraines, drumlins)

Man-induced (tailing piles, dredging piles)

USAETL-CRS

VEGETATION

The results derived from an analysis of vegetation patterns can be used to provide information about the vegetation itself in terms of type, density, vigor, stem diameter, etc., or to provide information about other terrain characteristics and climate. Air photo scales suitable for engineering soils evaluation and environmental data base preparation, i.e. in the 1:20,000 scale range, are too small for use in species identification. This task usually requires scales of 1:5,000 and larger. On the smaller scales, however, vegetation types or large pure stands can be identified and boundaries established between groups. These boundaries are frequently associated with changes in soil texture, soil moisture, topography, and orientation and give supportive information to factor boundaries established in earlier phases of the analysis. Knowledge of landform and soil within an area can frequently set the basis for a fairly accurate prediction of vegetation types. The vegetation patterns can also provide some information about climate. A mixed hardwood forest with a closed canopy and in a temperate region requires some 40-45 inches of rain per year. Progressively less rain means progressively less tree cover and an increase in other vegetation types. These relations are not exact but they can provide qualitative information about the area in question. Under certain conditions, usually in subhumid and arid regions, a vegetation type or species can be a unique indicator to such things as the soil mantle depth or soil type. Although there are several ways of classifying vegetation, some of them task oriented, a first-order breakdown based solely on photo patterns usually includes the following:

Forest	Closed Canopy Open Canopy	Sufficiently open to expose ground surface and subarbooreal layers to observation (50–75% trees).
Shrubs	Closed Canopy Open Canopy	
Mixed trees and grassland		About 50% of each.
Grasslands		
Agricultural	Plantations Cropland	
Wetlands		
Barren		

USAETL-CRS

CULTURAL

As in the case of vegetation the analysis of cultural patterns can be done for two purposes: to derive information about the culture itself and to use the cultural patterns to derive information about other factors. As an example of the first purpose, the economic characteristics of a given society can be deduced through an analysis of the cultural patterns. As an example of the second, a pattern of cultivated fields, such as the alternating tones of fallow farming on a flat surface, can provide clues as to soil texture and general climate. Cultural information is needed for many different purposes, e.g. economic evaluation, planning, military operations, etc. As a result, no single classification system satisfies all users. Classification systems are usually tailored to the problem at hand. Complicating the issue is the fact that most classification systems are some combination of land cover and land use categories. Land cover can be determined by image analysis. Identifying the land use, however, frequently rests on ground determination. Based solely on photo patterns, i.e. without auxiliary information, one can bound and trace the following first-level categories. Some second-level categories can also be obtained directly from imagery.

Structures. This includes patterns for all types of buildings, ranging from multibuilding farmsteads to metropolitan development.

Transportation and Communication. This includes highways, railroads, airports, canals, pipelines, transmitter towers, power lines, etc.

Agricultural and Livestock. This category includes cultivated fields, orchards, plantations, pasture, feed lots, etc.

Recreation. This includes those areas that have little or no structural development, but do show patterns that link them to some activity such as golf, skiing, camping, etc.

Special. This category is for cultural features that do not readily fit into other classifications, such as quarries (including gravel pits), cemeteries, transition zones, etc.

Natural. This classification is for those areas that do not show cultural patterns and which cannot therefore be assigned into any cultural category. Many of these areas will be identified on the factor patterns of drainage, vegetation, and surficial geology.

PHOTO TONES AND TEXTURE

Photo tones and textural patterns can provide information about specific materials or conditions, as well as provide information to support conclusions developed during the analysis of other factors. In most cases these patterns are associated with areas of relatively bare or exposed soil and rock, or with an area of uniform vegetation cover. Although photo tones and texture are important sources of information, care must be taken in evaluating them, especially those of soils, because climate and season greatly influence the development and detectability of these patterns. For instance, it is generally true that well-drained soils record as light tones or colors in a photograph and poorly drained, fine-textured soils tend to record as dark tones and colors. Under some conditions, however, these general statements are not true. A dry mound of sand on a sand plain in a humid region can show as a light tone against a darker background although the materials are the same for both the plain and the mound. The tone will be different due to the influence of topographic position of the mound on its drainage characteristics. The mound would probably show as a lighter tone than its background. In an arid region a sand dune on a sand plain will probably have tones very similar to those of the plain. Soil tone patterns can also alter their contrast, and even disappear, as a function of season or local weather conditions. With respect to soils, tones and textural patterns can provide information about identity, origin, uniformity, horizon development, moisture relations, etc. For instance, on panchromatic photography silt has a bright, uniform photo tone and a silky texture. Soils derived in glacial till generally show intricate patterns that are related to the complex character of the mantle. As examples, soils of the Wisconsin glacial till show an intricate mottling of light and dark gray tones that are related to different soil texture and moisture conditions; Illinoian till is characterized by a light fringing around the gullies, which is indicative of a soil profile development. Other tone patterns are associated with marks left as a result of wind action, or flowing water, which, in themselves are indicative of the nature of the surficial materials. With respect to rocks, tone and texture can provide supportive information as to type. In igneous rocks, for example, the mafic classes such as basalt and gabbro have dark photo tones. The silicic rocks such as granite tend to have lighter tones. In many subhumid and arid regions, however, the rock surfaces can be covered with another material such as lichens, desert varnish, or alterations produced by weathering which can darken or lighten the surfaces of the rock. The tones that are recorded by the sensor represent some unknown mixture of bare rocks, weathered surfaces, varnish surfaces, and lichen-covered surfaces. In some instances this cover can be as much as 80%, thereby causing a light colored granitic rock to have a very dark, almost black, photo tone. With respect to vegetation, tone and texture can provide information about composition or vegetation type.

SPECIAL

This pattern category includes items that do not easily fit under other factor headings or items that, though discussed elsewhere, are in themselves sufficiently direct indicators of identities and conditions that they warrant additional evaluation. Furthermore, this part of the analysis serves as one more checkpoint to examine the imagery for clues to support previous findings or suggest new relations or identities. Frequently these patterns depend on some inherent quality of the material or on some inherent nature of an action or force. When this is so, they can be important to such matters as evaluating construction sites, assessing potential instability, locating ground water, etc. For example, wind-blown silt deposits have an internal vertical structure that accounts for some patterns that serve as direct indicators of the presence of such material. These include the pinnate drainage pattern, flat-bottomed steep-sided gullies, terracettes and pinnacles on gully walls, and vertical road cuts. The pinnate drainage pattern, gully cross section, and road cuts would be evaluated under their respective sections. Terracettes and pinnacles, too small to be considered as landforms, would probably be evaluated within this category. As another example, slumps and tears in an otherwise smooth valley wall are indicative of instability and potential engineering problems. Patterns that merit special attention include joints, fractures, and faults; soil slumps, landslides, mudflows, and tears; certain landforms that are direct indicators of materials or conditions (barchan dunes, drumlins, colluvial slopes, etc.); and some patterns of drainage, erosion, and tones.

USAETL-CRS

SEDIMENTARY ROCKS

Sedimentary rocks are formed by the compaction and cementation of particulates, or grains, that have settled out of a transporting medium of water, wind, or ice. The grains that form these rocks are produced by the weathering and disintegration of pre-existing rocks or by chemical precipitation and are deposited as horizontal layers or beds, with the oldest deposit on the bottom and the most recent at the top. This bedding is characteristic of sedimentary rocks. There are two main types based on origin: clastic and chemical.

Clastic rocks. Clastic rocks are those formed by the weathered products of pre-existing rocks and are made up of particles ranging in size from boulders to clay. The common names given to these rocks are descriptive of the particle size, i.e. conglomerate (boulder to sand-sized particles), sandstone (sand-sized), silt stone (silt-sized), and shale (fine silt to clay-sized). The physical characteristics of these rocks, such as color and hardness, are determined by the mineralogy of the grains and the type and degree of cementation binding the grains together. Conglomerate and sandstone, for example, are usually composed of strongly cemented, resistant minerals such as quartz and are resistant to weathering, whereas shale is very weakly cemented and is softer.

Chemically deposited rocks. These rocks are formed by minerals precipitated from solution, secreted by organisms, or left as a residue from evaporation. They are more susceptible to chemical weathering and dissolution than the clastic rocks. The most common of the chemical sediments is limestone, which is composed of calcium carbonate in the form of calcite. Most limestones are of marine origin and were originally deposited as a limey mud on the ocean floor. Some limestones could be called clastic as they are composed of fragments of shells or coral cemented together. Dolomite is similar to limestone in appearance, but is somewhat more resistant to chemical weathering. Limestone and dolomite have the widest distribution of this group of rocks. Evaporites are formed by the evaporation of mineral bearing waters, usually in an arid environment. They are not as widely distributed or as abundant as limestone and dolomite, but are important from an economic standpoint. The evaporites are usually softer than other sedimentary rocks and are highly susceptible to chemical weathering. Gypsum and rock salt are the most common of the evaporites. As with most natural phenomena, sedimentary rocks do not always fall into clear-cut classes. It is possible, therefore, to have clastic sediments and chemical sediments being deposited at the same place and at the same time, giving rise to combinations such as sandy limestone, silty sandstone, gypsiferous sandstone, and so on for as many combinations as there are sizes and chemical classes.

COMPILER: J. Ponder Henley, USAETL.

**SEDIMENTARY ROCKS
SOLUBLE ROCKS**

Rocks formed from chemical sediments (precipitates or evaporites) are susceptible, in varying degrees, to dissolution. The rate of chemical weathering is dependent on the solubility of the rock, the presence of a solvent, and adequate drainage to remove the dissolved products. Limestones are the most widely distributed and recognized of the chemical sediments, and their spectacular cave systems with solutional and depositional features are well known. Most limestone is of marine origin, the calcium carbonate being deposited directly by chemical precipitation from sea water or deposited by organisms. Coral, bryozoans, and some algae have calcareous skeletons which form reefs, the voids of which can be filled with detritus or precipitated calcium carbonate to form a solid rock mass. All the shells of marine animals, such as gastropods, pelecypods, and brachiopods, contain calcium carbonate, and they can be cemented together into a limey matrix to form another type of limestone. In calm water very fine-grained limey mud can accumulate, forming a smooth compact limestone. In its purest form, limestone is composed of the mineral calcite (calcium carbonate). Many formations, however, contain varying amounts of impurities such as chert, sand, or clay minerals which can affect the weathering characteristics. The solvent available for the dissolution of limestone is water from atmospheric precipitation. Limestone is only slightly soluble in pure water. Rain and glacial melt water contain varying amounts of carbon dioxide, which produces a weak carbonic acid solution. This carbonic acid reacts with the calcium carbonate to produce calcium bicarbonate, which is soluble in water and is carried away. The chemical reactions and the changes in equilibrium are complex. Factors that influence the rate of dissolution include the presence of organic by-products and calcium dioxide in the soil, temperature of the solution, the amount of rainfall, and purity of the limestone. As impurities increase, especially the more granular types (sand and silt), weathering becomes a combination of mechanical and chemical.

Dolomite, a calcium magnesium carbonate rock, is similar to limestone in formation and appearance. Although it is generally considered to be less soluble than limestone, solution features are common in dolomite.

Evaporites. Gypsum (calcium sulfate) is the most abundant of the evaporite rocks at the surface, and is much more soluble than limestone or dolomite, especially in higher temperatures. Gypsum is usually more evident in arid areas, preserved because of the lack of rainfall.

The chloride rocks, the best known being halite (sodium chloride, or rock salt), are even more soluble and rarely persist as landforms.

COMPILER: J. Ponder Henley, USAETL.

SEDIMENTARY ROCKS
SHALE

Shale is a fine-grained clastic sedimentary rock and is the most common and widely distributed member of this group. It is formed by the compaction and induration of mud or silt and clay particles. Although shale contains silt, and at times larger particles, it always has an appreciable amount of the clay minerals. A fine silt represents the lower limit of particle sizes that can come from a grinding process, a size that is from about 0.002 mm to perhaps 0.005 mm (2–5 μm). Clay particles are the result of chemical reactions (alteration, decomposition, recrystallization) and have sizes less than 0.004 mm or 0.005 mm, depending on the classification used. Many of the particles are less than 0.002 mm. Being this small, the effects of surface charge are very large, and the particles cling together, a property called cohesiveness. Being a sedimentary rock, the structure of shale is a layered one, with the layers being finely stratified and having thicknesses that are but fractions of a millimeter. It has a fissility that is parallel to the bedding plane, i.e. it readily splits into thin sheets parallel to the bedding plane. If the rock is more massive and not fissile, it is a mudstone, siltstone, or a clay stone, depending on the grain size distribution. There are several classifications for shale, usually based on the relative percentages of clay, silt, and other material contained in them, but no one scheme is used universally. For example, there are argillaceous (clay) shales, arenaceous (sandy or siliceous) shales, calcareous (limey) shales, ferruginous (iron rich) shales, and carbonaceous (organic) shales. Clay shales are a valuable economic resource, and for commercial purposes are usually classified as kaolin, ball clay, fire clay, bentonite, fullers earth, and miscellaneous clay.

Because of the very small particle sizes and the resultant small pore size, shales are essentially impermeable, and intergranular cementation does not occur. Consequently, shales have little resistance to erosion and they are easily affected by mechanical weathering. Although shale can be indurated enough so that it does not fall apart when wet, it is usually relatively soft and easily broken. A shale can take on one of several different colors; for example, red, yellow, brown, blue/green, gray, black, and in some instances a very light gray. In general, shale is less durable than sandstone and limestone. Some clay shales and the residual soil covering them can absorb water and show a tendency to expand or shrink if they become wet or dry.

Engineering Characteristics and Problems. The residual soil mantle over a clay shale is plastic, cohesive, and has little or no dry strength. In general, the problems associated with clay shales are poor subgrade support, pumping, and poor natural drainage. Subgrade support and compaction of shale for fill present problems because of the expansive nature of clay shales when wet. Because of the poor natural drainage and the fissile nature, shales can also become a problem in stability. For example, ground water can collect on a shale's impervious surface, especially if located below an aquifer, and if this bed is dipping, this lubricated surface can cause sliding and slumping of the material above it.

COMPILER: J.N. Rinker, USAETL.

IGNEOUS ROCKS

Igneous rocks, formed from the cooling of molten material (magma), are divided into two groups: plutonic (intrusive), rocks that solidify deep within the earth's crust, and volcanic (extrusive), rocks that solidify on or near the surface of the earth. Chemical composition in both types of igneous rocks ranges from silicic to mafic, i.e. from rocks composed of light-colored minerals containing large amounts of silica to those composed of dark-colored minerals containing less silica and enriched in iron, magnesium, and calcium.

Plutonic Rocks. Plutonic rocks are formed from molten material that cools slowly deep within the earth's crust and are, therefore, coarse grained. Granitic magmas, for example, may be emplaced as deep as 20 kilometers below the surface; other magmas are emplaced at greater depths. Plutonic rocks appear on the surface of the earth only as the result of uplift and/or erosion. The most common forms of plutonic rocks are batholiths, dikes, and sills. Batholiths are very large bodies, usually formed of granitic rock, that are more than 100 sq. km. (40 sq. mi.) in diameter; dikes are narrow, relatively small linear bodies that cut across adjacent layers; and sills, similar to dikes in size and shape, parallel adjacent layers.

Common plutonic rocks are granite, diorite, monzonite, and gabbro. Granites, the most common, are composed of highly silicic, light-colored minerals, primarily quartz, light-colored plagioclase feldspars, potassium feldspars, and mica. In addition to forming from molten materials, granite can form as a result of metamorphic processes. Diorite and monzonite are medium grained and intermediate in color and composition, containing intermediate composition plagioclase, biotite, hornblende, and/or pyroxene and quartz. Diorite is intermediate in grain size, but usually is treated as a "granitic" rock. Monzonite can be coarse grained. Gabbro is dark in color, mafic in composition, and relatively rare; it consists primarily of dark-colored plagioclase, pyroxene, hornblende, and olivine. Pegmatites, very coarse grained rocks of granitic composition (crystals are often measured in meters), are also relatively rare. They usually occur as veins and form during the last stages of development of, and in association with, granitic batholiths.

Volcanic Rocks. Volcanic rocks are fine grained because they are formed from molten material that cools rapidly on or near the surface of the earth. Some volcanic material, such as obsidian (the most common volcanic glass), cools so rapidly that it is grainless. Volcanic rocks, forming as deep as several hundred meters below the surface of the earth, are divided into two groups: flow materials that result from quiet, non-explosive eruptions from volcanos and fissures; and pyroclastics that form from molten material explosively erupted into the air.

Flow Materials. Common flow materials are basalt, andesite, and rhyolite; basalt is the most common. The primary mineral constituents in basalts are dark in color, and include dark-colored plagioclase, pyroxene, and olivine. Andesite, the fine-grained equivalent of diorite, is intermediate in color and composition. The light-colored silicic rhyolite is the fine-grained equivalent of granite.

Pyroclastics. Pyroclastic rocks are usually fine grained. The most common are volcanic ash, pumice, and tuff. Pyroclastic rocks usually are intermediate to highly silicic in composition, but can also be mafic (volcanic bombs). They often contain large amounts of volcanic glass, and are normally medium to light in color. Pyroclastics, much less common than flow materials, are carried and deposited by wind and water and often form layered sequences.

Igneous rocks are important economically because the fluids associated with them during formation contain high concentrations of valuable elements. For example, gold, silver, copper, and uranium occur in veins associated with igneous rocks, and rare metals, such as lithium and beryllium, commonly occur in pegmatite minerals.

**TRANSPORTED - AEOLIAN
LOESS (WINDBLOWN SILT)**

Loess is an unconsolidated, or weakly consolidated, deposit of windblown soil that comes mostly from river flood plains. These deposits, which occur mostly in plain or plateau regions, range in thickness from a few centimeters to as much as 200 meters. Usually they are calcareous in nature (either calcium or magnesium carbonate) and consist mostly of angular grains of silt-sized particles (approximately 0.075 to 0.002 mm) with lesser amounts of very fine sand and clay. In general, the particle sizes decrease with increasing distance from the source. Most frequently the silt-size particles are quartz, i.e. quartz is common to all loessal deposits.

Debate continues as to the mode of emplacement, as well as the origin of loess. The prevailing view is that the sediment was produced by the grinding action of glaciers on underlying rocks. Later, the particles were deposited downstream from runoff from melting glaciers, and subsequently reworked and carried by the wind to be deposited on downwind upland surfaces.

Loess has a vertical microtubular structure which supports a capillary rise of as much as 9 m (30 feet), and which is responsible for forming the characteristic steep erosional faces. Loess that has not been deeply weathered has a high porosity (50-60%),¹ and an in-place dry density that ranges from 66-104 pounds per cubic foot.² It is usually well drained internally, with the vertical permeability being several times greater than the horizontal permeability. It is remarkably uniform in physical properties, easily eroded when exposed to running water, and forms a fertile soil.

Loessal deposits are distributed throughout the world. Within the United States loess can be found in Washington, Idaho, South Dakota, Nebraska, Iowa, Kansas, Illinois, Kentucky, Tennessee, Mississippi, Indiana, and Ohio. There are deposits in Europe that constitute an irregularly shaped rich farming belt through northeastern France, Belgium, Germany, Hungary, Poland, Czechoslovakia, Rumania, and into southeastern Russia. There are deposits in north China and throughout the basin of the Yalu River. In South America deposits can be found in Argentina, Paraguay, and to some extent Uruguay. There are also deposits in northern Africa, Israel, Australia, and New Zealand.

Engineering Characteristics and Problems. Although of low density, this material, when dry has a fairly high strength because of the clay binder. This strength can be lost because of wetting. Remolded loess has a greatly reduced permeability, is only moderately compressible, and has a low cohesive strength.³ Road cuts, other than near vertical, will be unstable and gradually erode back to the stable steep configuration, unless preventative measures are taken. The supportive properties are usually good if the material is compacted properly. Once the vertical structure is destroyed, which is easy to do, the material takes on other characteristics, and presents the engineer with a different set of problems. For example, when dry, the material is loose, impossible to compact, and easily removed by wind; and when saturated, it can become quick. These latter characteristics are also of concern when considering problems associated with cross-country mobility.

WATER DEPOSITS

Water-deposited materials are formed from sediments eroded and weathered from earth surface materials (rocks, soils, and other deposits). They cover a large portion of the world's land area and are important because they provide excellent sites for highways, airports, and other construction projects, and because of their economic value as sources for granular material. They range from minor deposits associated with the beds and banks of small streams to very large deposits such as the outwash plains formed from the erosion of adjacent mountains. The Great Plains of the United States are of this latter type. The depositing medium is flowing water, which has the ability to sort material by particle size as a function of the speed of the current. Furthermore, the telltale clues left by flowing water, i.e. ridges, channels, and current marks in the form of linear and curvilinear tone streaks are important indicators of these deposits.

These materials can become indurated, consolidated, or cemented, which alters both the structural characteristics of the mass, as well as the identifying surficial patterns. In many places, water-deposited materials of the Great Plains and the Coastal Plain of the U.S. have become rock-like through long periods of time, and no longer exhibit the surface patterns associated with water deposits. The air photo interpretation of water-deposited materials depends on relative age and erosional history; texture of the material and of the overburden; degree of induration, cementation, or consolidation; topographic position; climate; and the nature of the original topography covered by the material. There are several ways to classify water-deposited materials and we have elected to start on the one based on information in Frost (1953)¹ because it is oriented towards the use of air photo patterns.

Alluvial Deposits

- Fluviatile Plains
- Intermontaine Basins
- Stream Flood Plains
- Stream Terraces
- Deltas

Marine Deposits

- Coastal Plains (Estuarian Plains, Tidal Flats, Terraces)
- Miscellaneous Shore Features
 - (Beaches, Spits, Bars, Tidal Marshes, Reefs,
 - Barrier Beaches, Beach Ridges)

Lacustrine Deposits (Nonglacial Lakebeds)

- Tertiary
- Pleistocene
- Recent

Glacio-Fluviatile Deposits

**ORGANIC SOIL
PEAT AND MUCK**

Organic soils are formed by the sequential deposition of vegetative remains on the bottoms of shallow ponds, bogs, marshes, and swamps, where they slowly undergo anaerobic decay. Structure of organic deposits is that of a layered system that varies in the nature of the original plant tissue and in the extent of decomposition. These layers can later become soil horizons. Organic soils are differentiated on the state of decomposition. Nondecayed and slightly decayed deposits are called peat, and those deposits that are fully decomposed or nearly so are called muck. In peat deposits one can identify plant parts and plant species. The texture of these soils ranges from fine to coarse as a function of the nature of the plant residue. In muck deposits plant parts cannot be identified and the soils are fine.

Organic soils are dark brown to black and are light in weight when dry, having about one-sixth the bulk density of a mineral soil. They have a high water holding capacity, holding three to four times their dry weight in moisture. Some slightly decomposed peats can hold 12-20 times their dry weights in water.¹ On the other hand, dry mineral soils can usually hold only one-fifth to two-fifths of their dry weights as water. Organic soils have a much larger surface area than even mineral soils such as clay, and consequently, they have a more pronounced colloidal nature. Plasticity, however, is low. In general, these soils are porous and easy to cultivate when dry; and if the structure has been destroyed, these soils are easily eroded by the wind. In dry seasons peat and muck deposits can burn for weeks if they catch fire, and such fires are difficult to extinguish. In addition to being valuable agricultural soils, these materials are used in greenhouses, in nurseries, on lawns, and as a fuel.

Although the organic soils are nowhere near as extensive as the mineral soils, they can be found throughout the world where conditions are favorable. A great portion of the world's deposits (60%) occur in Russia.² Within the U.S., these deposits are scattered throughout the country, although the vast majority are in glaciated areas. The Pleistocene glaciation set the stage for the development of shallow ponds, bogs, and swamps by leaving a suitable topography and by impeding, if not blocking, drainage-ways.

Engineering Characteristics and Problems. Because these soils are highly compressible, they should be avoided as foundation materials. If this cannot be done, compensatory techniques must be used, e.g. excavation and backfill, use of piles and bridges, or causing compaction by surcharging.³

**SEDIMENTARY ROCKS
SANDSTONE — FLAT-LYING**

Sandstone is composed of sand-sized particles cemented together. Most frequently the particles are quartz, and the cementing agent can be calcium carbonate, iron, or silica. The characteristics of sandstone depend on the origin of the sand and on the type of deposition, i.e. aeolian, alluvial, or marine. The beds can be massive or thin, and cross bedding is common. The relative strength and resistance to weathering of sandstone are determined by the mineral composition of the grains, the type of binder, and the thickness of the beds caused by depositional variation. For example, sandstone cemented by silica is resistant to erosion and weathering. Other sandstones can be so weakly cemented that they easily break apart into their component grains. Sandstones that are cemented with calcium carbonate develop deeper soil mantles than sandstones having a siliceous binder. As the calcium carbonate content increases, such rocks take on the patterns of limestone. On exposed sandstones with rough topography, surface water carries away many of the particles, resulting in a thin soil mantle. Because sandstones can be porous, they are important reservoirs of water. Although they usually occur interbedded with other sedimentary rocks, one can find massive units up to 130 meters (approx. 400 feet) thick.

Landform. The resultant landform depends on the climate, as well as the thickness of beds. In arid regions, sandstone is a mesa former and the landform is blocky, flat-topped with vertical sides, and contains box-like canyons and gullies with vertical walls. Pinnacle rock forms are common and talus piles are usually found at the base of cliffs. Wind abrasion can carve the blocks into unusual shapes. In humid regions, the landform associated with massive beds is slightly crested, with a vertical face and talus piles at the base of the face. Dense vegetation can cause a rounding or smoothing effect. Soft sandstones have sharply crested ridges and V-shaped valleys. Thinly bedded sandstones also tend towards this type of landform.

Drainage-Plan. Dendritic on a broad regional basis. The local pattern can vary in its arrangement from dendritic to rectangular with many right angle turns in the streams caused by jointing in the rock. The angles between gullies, tributaries, and major streams are relatively sharp, i.e. they are not rounded as in the case of limestone.

Drainage-Elevation. In cross section the gullies are long, straight, steep, and V-shaped, and the valleys containing them are V-shaped. Areas between closely spaced gullies are sharply crested. Gullies developed in a soil mantle on soft sandstone are sharply V-shaped. A residual soil of sand and clay produces U-shaped gullies, whereas one of silty clay produces broader and softer V shapes.

Erosion. By water, wind, and gravity. Sandstone is fairly resistant and not easily eroded by running water. Depending on the climate, sandstone weathers to blocky pieces which are slowly reduced to sand, or it weathers directly to sand. This sand is removed by running water or by wind action. Weathering is easier along joints and fractures, especially in arid climates, and can form a series of widened grooves on the surface. Wind erosion or, more accurately, sand blasting can cause an outcrop to appear "honey combed" or "moth eaten." Unless precautions are taken, shallow residual soils are easily erodible in farming areas. Talus accumulations attest to the gravitational influence.

Deposition. Usually in the form of talus slopes in both arid and humid regions. The eroded sand can be deposited as fans at gully mouths, as valley fill, or carried out to form deposits in a basin.

Vegetation. A forest cover in humid regions. Because sandstone is often a water-bearing rock, it will support some vegetation even in subhumid areas, and provides a basis for separating sandstone from other sedimentary units. In arid regions vegetation is sparse and is usually concentrated along drainageways and in joints.

Cultural. Orchards are common in humid areas. The shallow soils are not usually suitable for tillage. Where farming does occur contour plowing is frequently practiced as a means of reducing surface erosion.

Tone and Texture. If not obscured by vegetation the tones of sandstone and residual sandy soils tend to be light. The tones tend to be slightly darker with increased clay and silt content.

**SEDIMENTARY ROCKS
LIMESTONE — FLAT-LYING
HUMID, SUBHUMID AREAS**

Limestone is made principally of calcium carbonate, a substance that is slightly soluble in the weak carbonic acid formed from atmospheric carbon dioxide and rain-water. In areas of sufficient rainfall, the slightly acid runoff trickles down through and along joints and fractures, slowly dissolving the limestone and gradually enlarging the cracks. Intersections of vertical fractures are gradually enlarged into sinkholes. Caves and passages can become so large that the rock roof collapses from its own weight. With time the sinkholes, voids, and passages become ever larger, and eventually coalesce to form interconnected solution valleys. As the limestone is dissolved away, particulate matter that settled out during the formation process is deposited as a residual soil.

Landform. Plain. In youth the landform is a sinkhole-studded plain with poorly developed sinkholes in early youth and well-developed ones later. Relief can be as much as 25 meters (refer to Indicator 0019). In maturity the form is a karst plain with large, deep sinkholes, collapse features, and vertically walled solution valleys that are usually flat-bottomed, and with relief ranging from 100 to 200 meters (refer to Indicator 0021). Tributaries to the main solution valley are short and stubby. In the plan view of youthful and mature forms, the intersections of drainageways are well rounded, appearing scalloped in places. In old age the landform is a mound-covered plain. The dome-shaped mounds are remnants of the former sinkhole divides. In tropical regions limestone frequently shows a knobby surface.

Drainage—Plan. Discontinuous in youth and maturity. Although some drainage occurs through the porous soil and into the joints and fractures, most of the drainage is by way of the sinkholes, which are circular in horizontal beds. If a sinkhole drainageway becomes clogged, a pond results. As the landscape matures and solution valleys merge, areas of connected drainage develop which are usually dendritic in pattern.

Drainage—Elevation. Surface gullies rarely exist. Sinkholes are gently rounded depressions in youthful terrain, and gradually evolve into deep, steep-sided, funnel-shaped holes.

Erosion. Degradation occurs by chemical solutioning, scouring by running water, and gravitational collapse.

Deposition. Other than the accumulation of the residual soil, depositional patterns are not developed.

Vegetation. A closed forest canopy in humid regions. In cleared areas of the youthful landform trees are frequently left in many of the sinkholes.

Cultural. The residual soil that accumulates is a very good soil and can support a variety of agricultural practices, topography permitting. Quarries are frequently evident.

Tone and Texture. The rock color usually ranges from a light to a dark gray, and the soil color from yellowish-brown to red. In humid areas vegetation obscures both the soil and the rock. In less humid or cleared areas the soil shows as a light photo tone with darker circles or spots for the sinkholes.

Special. Fractures and joints are apparent on aerial photography as surficial line traces, as segments of drainage, and as flat walls of sinks and collapse features. Sinkholes tend to align with the fracture pattern.

Engineering Characteristics and Problems. The weathering of limestone can produce a relatively deep residual soil mantle. In humid areas a typical soil profile would show a top horizon consisting of a yellowish-brown silty soil of some 50 cm (2 feet) thickness; a relatively thick bright red B horizon of clay and silty clay; and a rather whitish C horizon of plastic clay containing limestone fragments. The more important engineering problems are associated with road cuts, the need to avoid or fill sinkholes, the possibility of subsurface voids, and varying subgrade conditions. Even though the top horizon soils are well drained internally, they become poorly drained when their structure is destroyed by compaction.

COMPILERS: Jack N. Rinker and Robert E. Frost, USAETL.

**SEDIMENTARY ROCKS
LIMESTONES AND SHALES
FLAT-LYING — HUMID**

In many places sedimentary rocks exist as alternating beds of limestone and shale. Differential weathering of interbedded hard resistant limestones and soft shales can develop several patterns, depending on the thickness of the beds. If the beds are thin, the slopes tend to be smooth. Thicker beds can show as slope changes, as well as tone changes that are in the form of contour-like bands that outline the hills. In 1:20,000 scale aerial photography slopes appear relatively smooth where the beds are less than half a meter in thickness. The combination of weathering, erosion, impervious and hard limestone, and impervious and soft shale units, tends to develop a compound slope with the upper section steeper than the lower. The lower slope is mantled with a colluvium of limestone fragments embedded in plastic clay. This mantle, which becomes thicker towards the toe, tends to protect the in-place rock from further degradation.

Landform. A flat-topped dissected plain with softly rounded slopes in both plan and elevation. In humid areas angularity is absent. Hill slopes are not uniform but are steeper in the top one-half to two-thirds and flare out in the bottom portion. The upper, steeper slope represents rock in place; the lower, gentler slope represents colluvial material; and the break in slope marks the transition. Spurs, uniform in height and general slope, extend out from the upland areas. The contour that represents the base of the hills is rounded, arcuate, and in places, scallop-like.

Drainage—Plan. Although the overall regional pattern appears dendritic in form, a close examination will usually reveal the influence of joints and fractures. Larger streams and whole valleys tend to meander. The upland surface can show tones, and sometimes depressions, associated with sinkholes. On the hill slopes many straight parallel gullies can be found on the colluvium. These cannot be detected if there is much vegetation. The angles between gullies and tributaries are rounded.

Drainage—Elevation. Large gullies that are tributary to important collector valleys have a cross section profile that resembles a broad, open, and rounded "V." In humid regions, gully shapes are difficult to observe because of vegetation.

Erosion. By abrasive scouring, weathering, and gravity. Landslides can occur in the colluvial material.

Deposition. None.

Vegetation. In humid areas such a region will be tree covered or cleared for farming. In semiarid regions it will usually be grass covered.

Cultural. Farming in humid regions and grazing in semiarid locations. In arid regions the soils are usually too thin for crops. Contour farming practices are frequently followed. Highway alinement usually follows ridges or valley bottoms where possible. Because colluvium is an unstable material, landslides are a constant problem to construction and engineering efforts.

Tone and Texture. In humid regions vegetation masks the tones and color of the underlying material. In arid regions, and if the beds are thick enough, a contour-like banding can be seen. The lighter banding marks the limestone beds, and the darker banding indicates the shale layers.

Special. The flaring out of the lower slopes in what is known to be a series of sedimentary rocks is an indicator that points to the likely presence of interbedded limestone and shale. This is also a direct clue to the existence of colluvial material and to the engineering problems associated with its instability.

Engineering Characteristics and Problems. Insofar as construction operations are concerned, several problems are associated with this type of area. Usually these problems are in terms of drainage, compaction, subgrade conditions, and landslides. The colluvial mantle can become unstable from excess water, cutting the toe, loading the surface, etc., any of which can induce landslide activity.

COMPILERS: Robert E. Frost and Jack N. Rinker, USAETL.

**SEDIMENTARY ROCKS
SHALE — FLAT-LYING**

Shales are fine-grained (less than 0.005 mm) clastic sedimentary rocks produced by the compaction and induration of silt and clay-sized particles. They are the most common and widely distributed sedimentary rocks. Shale has a wide range in chemical composition as a function of the clay minerals within it. In terms of particle size distribution it can also include a wide range of nonclay components. For example, there are argillaceous (clay) shales, arenaceous (sandy or siliceous) shales, calcareous (limey) shales, ferruginous (iron-rich) shales, and carbonaceous (organic) shales. The structure is of the bedded type, with the beds ranging from very thin to thick. Shales are usually fissile, that is, they are easily split into thin layers parallel to the original bedding planes. In general, shales are not as durable as sandstone and limestone. Because shale is made of an impermeable material, intergranular cementation does not occur, and as a result it readily succumbs to simple mechanical weathering. Clay shales absorb water and have a tendency to expand and shrink as they become wet or dry.

Landform. Because there are many varieties of shale, there are many varieties of landform. Climate is also an important factor. In general, shales occupy troughs, or can be maturely dissected to form a softly rounded topography in humid climates; or rugged, severely dissected terrain in arid regions that have few, but torrential, rainstorms. Hard shales will have steeper slopes, but retain a rounded aspect. These landforms are not as controlled by geologic structure as are those developed on other sedimentary rocks.

Drainage-Plan. Dendritic. If the shales are soft, the intersections of branches and gullies will be rounded. Only when the shales are relatively hard will angularity appear in the plan view. In general, the finer the drainage net, i.e. the closer the spacing of the gullies, the finer the particle size distribution of the material. Thus, clay shales usually have a relatively dense or closely spaced drainage net. The basic pattern is modified by climatic conditions. In an area subjected to bursts of intense rainfall and flash flooding the drainage pattern is denser than for a similar clay shale in a region where the rain is more uniformly distributed throughout the year.

Drainage-Elevation. In cross section the gullies are rounded, almost saucer-shaped, and have long, uniform gradients. In sandy shales the gullies tend to have a cross section that is more of a broad V shape. In arid regions the slopes can be angular and steep because of scouring caused by flash flooding.

Erosion. By water primarily. The fine texture and lack of cementing agents make shale susceptible to mechanical weathering and erosion by running water. It is easily eroded in arid regions because of the lack of vegetation and the flash flooding.

Deposition. In addition to forming a residual soil mantle, the silt and clay particles weathered from shales can be transported from the immediate area and redeposited elsewhere as alluvial or lacustrine sediments. Because of their small particle sizes, they do not form fans at gully mouths.

Vegetation. In humid climates, shales will support a dense vegetative cover if the residual soil is deep enough. Side slopes too steep for cultivation or with soil too shallow for agriculture will be forested. The uplands can be cultivated. In arid climates the land is barren or very sparsely vegetated with shrubs or grass if a soil is developed.

Cultural. The primary economic pursuit is agricultural, which is climate dependent. High quality shale is used in making fired clay products and in making cement; therefore, quarrying operations and kilns are frequently present.

Tone and Texture. In arid regions the coloring is usually of a yellowish-brown, which gives a light photo tone in panchromatic imagery. In flat lands where gullying has not occurred the depressions are dark and the highs are light. In humid regions tones are usually obscured by vegetation.

Engineering Characteristics and Problems. The residual soil mantle over a clay shale is plastic, cohesive, and has little or no dry strength. In general, the problems associated with clay shales are poor subgrade support, pumping, and poor natural drainage. Subgrade support and compaction of shale for fill present problems because of the expansive nature of clay shales when wet. Because of the poor natural drainage and the fissile nature, shales can also become a problem in stability. For example, ground water can collect on a shale's impervious surface, especially if located below an aquifer, and if this bed is dipping, this lubricated surface can cause sliding and slumping of the material above it.

COMPILERS: J. Ponder Henley, Jack N. Rinker, and Robert E. Frost, USAETL.

IGNEOUS ROCKS

Of the three groups of rocks, igneous, metamorphic, and sedimentary, only the igneous rocks can be considered "original," for they are formed from the cooling of molten material. Igneous rocks are divided into two groups: extrusive rocks, which solidify on or near the surface of the earth, and intrusive rocks, which solidify deeper within the earth's crust. Chemical composition in both types of igneous rocks ranges from silicic to mafic, i.e. from rocks composed of light-colored minerals containing large amounts of silica to those composed of dark-colored minerals containing less silica and enriched in iron, magnesium, and calcium. The mafic rocks tend to be mechanically stronger than the silicic rocks because of their composition. Because their mineral components react more readily with water than do the mineral components of the silicic rock, the mafic rocks are less resistant to weathering in climates where water is abundant. In short, the mode of emplacement, the chemical properties, climate, weathering, and tectonic activity determine the characteristics of the photo patterns found on igneous rocks.

Landform. The air photo pattern produced by igneous rocks is more complex than the patterns of sedimentary and some metamorphic rocks because of the greater range in igneous rock composition and the tendency of such rocks to form random patterns. With the exception of such landforms as lava flows, the topography in areas of exposed igneous rocks tends to be that of rugged mountains and hills; escarpments and plains, however, are common. Depressions such as calderas and craters are characteristic of volcanic igneous landforms.

Drainage—Plan. The most common drainage patterns on igneous rocks are dendritic, indicating homogeneous composition over large areas, and radial, indicating the shape of the typical hill or mountain landform. Stream alignments usually are highly irregular, and straight stream segments are short. Stream density is generally low.

Drainage—Elevation. Stream channels in igneous rocks usually are V-shaped and quite deep, providing the high relief typical of igneous terrains. Waterfalls are common.

Erosion. Mechanical weathering of igneous rock predominates, but is often accompanied by chemical weathering, particularly in humid climates. Weathering in hot arid regions is almost exclusively mechanical. Erosion is concentrated along fractures.

Deposition. Areas of igneous rocks (excluding pyroclastics) usually form highlands, and are not, therefore, areas of deposition; most eroded material is carried out of the igneous region.

Vegetation. Vegetative cover on igneous rocks is more sparse than on metamorphic or sedimentary rocks in the same area; the less weathered and younger the surface exposure, the sparser will be the vegetation.

Cultural. Areas of igneous rocks are usually culturally unexploited, except where plains are formed. In these areas, agriculture is commonly the major activity. The most common use of other igneous terrain is for recreation.

Tone and Texture. Dark-colored rocks are composed of low silica minerals enriched in iron, magnesium, and calcium and appear dark gray to black in photo tone on panchromatic aerial photography. Light-colored rocks are high in silica and sodium and, as a result, appear light gray to white in photo tone on panchromatic aerial photography. Photo texture is related to grain size: the coarser grained the rock, the rougher and blockier the texture. Texture is also related to the density, direction, and attitude of joints.

Special. Almost all igneous rocks are jointed. Certain types of joints are characteristic of certain types of rocks, i.e. columnar joints are characteristic of basalt, and curvilinear sheeting joints are characteristic of granite.

COMPILER: Judy Ehlen, USAETL.

**IGNEOUS ROCKS
PYROCLASTICS**

Pyroclastic igneous rocks are formed from particles ejected from the crater of a volcano or a fissure. Particles range in size from silt (ash fragments) to boulders (volcanic bombs) that can be more than 4 meters in some dimension. The photo patterns of pyroclastic rocks are therefore distinctly different from those formed on flow materials.

Landform. Pyroclastics usually form low, rounded hills and plains. Two types of volcanos are formed of pyroclastic material: cinder cones and spatter cones. Cinder cones are small- to medium-sized volcanos formed of cinders (lava with a high gas content). Lava flows often extrude from the bases and sides of cinder cones. Spatter cones are small hills usually less than 20 meters (65 feet) high, and are formed of basaltic material with a low gas content. This material is ejected over short distances as small globs that stick together upon landing. Cinder cones and spatter cones often form lines along the fissure from which they are derived. Resistant pyroclastic rocks, such as tuff and welded tuff (tuff hardened by heat and/or pressure) cap the hills. In addition, welded tuff sometimes occurs in rings called maars, which are formed by underwater eruptions. Extensive fairly flat areas covered with pumice to a depth of at least several inches are relatively common near volcanos that have a history of violent explosive eruptions. Such plains are called pumice plains. Pumice is a highly silicic, glassy lava.

Drainage-Plan. Excluding the fine-grained ash deposits, drainage patterns on pyroclastics are usually subdendritic, rectangular, or radial. Surficial drainage is usually absent on the more porous pyroclastic materials, such as pumice, particularly when they are relatively young. The very dense dendritic drainage patterns on ash deposits are similar to those formed on fine-grained sedimentary rocks (e.g. shale), making differentiation between ash and shale difficult on aerial photography unless there are other volcanic features in the area. Radial patterns develop on cinder cones and spatter cones.

Drainage-Elevation. Stream channels in the finer-grained pyroclastics are often steep-sided and V-shaped, whereas in the more resistant pyroclastic materials, such as welded tuff, they are more irregular and angular, without the sharp V-shaped cross section.

Erosion. Fine-grained volcanic material that has been deposited by wind or water will erode in a pattern similar to that of any fine-grained sedimentary material. Because of the softness of such materials, they are easily eroded. Consequently, badlands-type topography is common. Material that has been welded is more resistant to erosion and will develop vertical slopes, often with pinnacles and fins (narrow, sharp ridges). Although water is the primary agent of erosion, it is possible that the wind plays some role in the formation of fins and pinnacles.

Deposition. Pyroclastic materials are either deposited near their source by gravity or are carried some distance by the wind. The average distance that fine-grained volcanic ash is carried is usually measured in kilometers, whereas volcanic bombs are usually deposited within a few meters of the vent. They are subsequently moved downslope by running water.

Tone and Texture. Pyroclastic material is usually silicic in composition, and is light in color and photo tone. Tuffs, ash deposits, and pumice are highly variable in color, ranging from pink, green, and buff, to gray and white. Volcanic bombs, which are basaltic in composition, are dark in photo tone, as are cinder cones and spatter cones. The textures of pyroclastic materials differ greatly. The most common pyroclastics are tuff and ash deposits, which appear smooth on aerial photography. Welded tuff appears coarse in texture because smaller particles have been welded together to form large, blocky aggregates. Cinder cones and spatter cones are usually rough and blocky in photo texture.

 @NASAARSET

Fundamentals of Aquatic Remote Sensing

Sherry L. Palacios, Ph.D.

Course Objective

- Provide an overview of aquatic optics, the remote sensing of water targets, and NASA Earth observation resources available for aquatic applications.

Credit: NASA/USGS Landsat; Geoscience Australis

Agenda

- Light and Water
- Fundamentals of Remote Sensing
- Aquatic Remote Sensing Data Products and Their Uses
- Accessing NASA Satellite Imagery
- NASA Satellite Data Processing Tools

Phytoplankton Bloom in the Arabian Sea

Credit: N. Kuring, <http://earthobservatory.nasa.gov/IOTD/view.php?id=85718>

Why Do We Observe from Space?

To Understand Earth's Processes on a Global Scale

SeaWiFS Chlorophyll
Credit: OBPB, NASA Goddard

Advantages of Remote Sensing of Aquatic Environments

- Synoptic coverage
- Temporal frequency needed to capture dynamic aquatic processes
- Observations of remote ocean locations, infrequently accessed by sea-based platforms

An aerial photograph of a coastal region. On the left, a river with a complex delta system flows into the sea. The land is green with some brown patches, possibly indicating different vegetation or soil types. The water near the shore is a light turquoise color, while the deeper ocean is a dark blue. A large, semi-transparent white rectangle is overlaid on the right side of the image, containing the title text.

Light and Water

Agenda

- Light and Water
 - How light propagates through the atmosphere and water column, and back to sensor
 - Constituents of the water column and their inherent optical properties
- Fundamentals of Remote Sensing
- Aquatic Remote Sensing Data Products and Their Uses
- Accessing NASA Satellite Imagery
- NASA Satellite Data Processing Tools

Phytoplankton Bloom in the Arabian Sea

Credit: N. Kuring, <http://earthobservatory.nasa.gov/IOTD/view.php?id=85718>

First, an Aquatic Optics Primer...

The Electromagnetic Spectrum

How Light Interacts with Water

Defining Remote Sensing Reflectance (R_{rs}) – or ‘Ocean Color’

$$R_{rs}(\lambda, 0^+) \cong C \frac{b_b(\lambda)}{a(\lambda) + b_b(\lambda)}$$

Inherent Optical Properties

a = absorption by...

phytoplankton (ph)

non-algal particles (nap)

colored dissolved organic matter (CDOM)

water (w)

b = scattering in forward (f) and backward (b) directions

How Light Interacts with Water

Defining Remote Sensing Reflectance (R_{rs}) – or ‘Ocean Color’

$$R_{rs}(\lambda, 0^+) \cong C \frac{b_b(\lambda)}{a(\lambda) + b_b(\lambda)} = \frac{L_w(\lambda)}{E_d(\lambda, 0^+)}$$

Inherent Optical Properties

a = absorption

b = scattering

Apparent Optical Properties

L_w = water leaving radiance

L_u = upwelling radiance

E_d = downwelling irradiance

R_{rs} = remote sensing (rs) reflectance

Inherent Optical Properties (IOPs) and the 'Color' of Water

$$R_{rs}(\lambda, 0^+) \cong C \frac{b_b(\lambda)}{a(\lambda) + b_b(\lambda)}$$

Light absorption (a) by phytoplankton (ph), non-algal particles (nap), water (w), and colored dissolved organic matter (CDOM)

$$a = a_{ph} + a_{nap} + a_{CDOM} + a_w$$

Light scattering (b) by particles in forward (b_f) and backward (b_b) direction

$$b = b_f + b_b$$

Inherent Optical Properties (IOPs) and the 'Color' of Water

Inherent Optical Properties (IOPs) and the 'Color' of Water

Inherent Optical Properties (IOPs) and the 'Color' of Water

- The typical human eye has color-detecting receptors that sense light at:
 - 420-440 nm 'blue'
 - 534-555 nm 'green'
 - 564-580 nm 'red'
- Water with high chlorophyll content looks green because it reflects strongly in the green part of the spectrum

An aerial photograph of a coastal landscape. A river with a light-colored, sandy delta flows into the ocean. The water near the shore is a vibrant turquoise, while the deeper ocean is a dark blue. The land is covered in green vegetation. A semi-transparent white rectangle is overlaid on the right side of the image, containing the title text.

Fundamentals of Remote Sensing

Agenda

- Light and Water
- Fundamentals of Remote Sensing
 - Spatial, Temporal, Spectral Resolution
 - NASA Satellites and Sensors for Aquatic Applications
 - Image “Correction”
 - Satellite Data Processing Levels
- Aquatic Remote Sensing Data Products and Their Uses
- Accessing NASA Satellite Imagery
- NASA Satellite Data Processing Tools

Phytoplankton Bloom in the Arabian Sea

Credit: N. Kuring, <http://earthobservatory.nasa.gov/IOTD/view.php?id=85718>

Types of Resolution

Spatial Resolution

- Decided by its pixel size
- Pixel: smallest unit measured by a sensor

Temporal Resolution

- How frequently a satellite observes the same area of the Earth

Spectral Resolution

- Ability of a sensor to define fine wavelength intervals
- Finer spectral channels enable remote sensing of different parts of the atmosphere

*Credit: Natural Resources Canada

Satellite (Sensor)	Spatial Resolution	Temporal Resolution	Spectral Bands
Landsat 8 (OLI)	15 m, 30 m	16 day revisit	9 bands (blue-green, green, red, near IR, shortwave and thermal IR)
Terra, Aqua (MODIS)	250 m – 1 km	2 times per day	36 bands (red, blue, IR, NIR, MIR)

How Do We Observe From Space?

Overview of Active & Passive Remote Sensing

- Satellites carry instruments and sensors to measure:
 - reflected solar radiation
 - emitted infrared and microwave radiation

Data Collection by Satellites

Atmosphere

- Clouds
- Aerosols
- Gases

Earth's Surface

- Snow/Ice
- Land (land use, vegetation)
- **Water**

Remote Sensing of Water Bodies

Reflected Solar Radiation (~color of water)

- Measured by satellite sensors
- Used to derive the properties of optically-active water constituents

- Suspended Sediments
- Algae
- Colored Dissolved Organic Matter
- Detrital Organic Matter
- Submerged or floating vegetation
- Oil

- Contaminants
- Pathogens

Coccolithophore Bloom, Norway

Remote Sensing of Water Bodies

Emitted Thermal Radiation

- Used to derive the surface temperature of water bodies

MARACOOS, ORB Lab, courtesy M. Oliver

A satellite image of a coastal region. On the left, a river with a complex delta system flows into the ocean. The land is green with some brown patches, indicating vegetation and possibly agricultural or natural terrain. The ocean is a deep blue, with a lighter turquoise area near the shore. A semi-transparent light blue rectangle is overlaid on the right side of the image, containing the title text.

NASA Satellites and Sensors for Aquatic Applications

Overview of NASA Satellites & Sensors for Water Quality Monitoring

- Currently several satellites observe water surface properties in:
 - the open ocean
 - coastal oceans and estuaries
 - many inland lakes
- A number of water quality parameters are operationally available from these satellites
 - e.g. temperature, chlorophyll-a

NASA Satellites & Sensors for Ocean and Coastal Systems

Satellite	Sensor	Parameter
Landsat Series (7/1972 - present)	• Thematic Mapper (TM) • Enhanced Thematic Mapper (ETM+) • Operational Land Imager (OLI)	• Spectral Reflectance
Terra (12/1999 - present)	Moderate Resolution Imaging Spectroradiometer (MODIS)	• Spectral Reflectance • Chlorophyll-a Concentration • Temperature • Colored Dissolved Organic Matter (CDOM) • Turbidity • Euphotic Depth
Aqua (5/2002 - present)		
Terra (12/1999 – present)	Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER)	• Spectral Reflectance • Temperature

NASA Satellites & Sensors for Ocean and Coastal Systems

Satellite	Sensor	Parameter
National Polar Partnership (NPP) (11/2011-present)	Visible Infrared Imaging Radiometer Suite (VIIRS)	• Spectral Reflectance • Chlorophyll Concentration
International Space Station	Hyperspectral Imager for the Coastal Ocean (HICO) (2009 – 2014)	• Spectral Radiance • Spectral Remote Sensing Reflectance
Plankton, Aerosols, Clouds, ocean Ecosystems (PACE) (proposed for 2022 or 2023)	Ocean Color Instrument	• Spectral Reflectance • Optional Polarimeter being considered

Landsat Satellites and Sensors

<http://landsat.gsfc.nasa.gov/>

- Near-polar orbit
- 10 a.m. equator crossing time
- Global coverage
- July 1972 – present
- 16 day revisit time
- Sensors:
 - MSS
 - TM
 - ETM+
 - OLI
 - TIRS

Landsat-7 Enhanced Thematic Mapper (ETM+)

<http://geo.arc.nasa.gov/sgc/landsat/l7.html>

- Flying on-board Landsat 7 polar orbiting satellites
- Spatial Coverage and Resolution:
 - Global, swath 185 km
 - Spatial Resolution: 15 m, 30 m, 60 m
- Temporal Coverage and Resolution
 - April 15, 1999 – present
 - 16 day revisit time
- Spectral Bands
 - 8 bands (major bands include: blue-green, green, red, reflected and thermal IR, and panchromatic)

- Spectral Bands
 - Bands 1-5, 7: 30 m
 - Band 6: 60 m
 - Band 8: 15 m

Landsat-8 Operational Land Imager (OLI)

<http://landsat.usgs.gov/landsat8.php>; <http://landsat.gsfc.nasa.gov/?p=5779>

- Flying on-board Landsat 8 (Landsat Data Continuity Mission – LDCM) polar orbiting satellite
- Spatial Coverage & Resolution:
 - Global, Swath 185 km
 - Spatial Resolution: 15 m, 30 m
- Temporal Coverage & Resolution:
 - February 11, 2013 – present
 - 16 day revisit time
- Spectral Bands
 - 9 bands (major bands include blue-green, red, near IR, shortwave and thermal IR, panchromatic)

Terra and Aqua

<http://terra.nasa.gov/>; <http://aqua.nasa.gov/>

Terra

- Polar orbit, 10:30 a.m. equator crossing time
- Global Coverage
- December 18, 1999 – present
- 1-2 observations per day
- Sensors:
 - ASTER, CERES, MISR, MODIS, MOPITT

Aqua

- Polar orbit, 1:30 p.m. equator crossing time
- Global Coverage
- May 4, 2002 – present
- 1-2 observations per day
- Sensors:
 - AIRS, AMSU, CERES, MODIS, AMSR-E

MODerate Resolution Imaging Spectroradiometer (MODIS)

<http://modis.gsfc.nasa.gov>

- On board Terra and Aqua
- Designed for land, atmosphere, ocean, and cryosphere observations
- Spatial Coverage and Resolution:
 - Global, Swath: 2,330 km
 - Spatial Resolution Varies: 250 m, 500 m, 1 km
- Temporal Coverage and Resolution:
 - 2000 – present
 - 2 times per day

Spectral Bands

- 36 bands (red, blue, IR, NIR, MIR)
 - Bands 1-2: 250 m
 - Bands 3-7: 500 m
 - Bands 8-16: 1000 m

Image Credit: <http://cimss.ssec.wisc.edu/>

National Polar Partnership (NPP)

http://www.nasa.gov/mission_pages/NPP

NASA/NOAA

- Polar orbit
- 1:30 p.m. equator crossing time
- Global coverage
- November 21, 2011 – present
- 1-2 observations per day
- Sensors:
 - VIIRS
 - ATMS
 - CrIS
 - OMPS
 - CERES

Visible Infrared Imaging Radiometer Suite (VIIRS)

<http://npp.gsfc.nasa.gov/viirs.html>

- Flying on-board NPP, polar-orbiting satellite
- Designed to collect measurements of clouds, aerosols, ocean color, surface temperature, fires, and albedo
- Spatial Coverage and Resolution:
 - Global, swath width: 3,040 km
 - Spatial resolution: 375 m – 750 m
- Temporal Coverage
 - October 2011 – present
 - 2 times per day

- Spectral Bands
 - 15 bands (major bands include visible, red, blue, green, short, middle, and long-wave IR)
 - Ocean Color Bands 1-7: 0.402 - 0.682 μm
 - Sea Surface Temperature Bands 12-13: 3.660 - 4.128 μm

Hyperspectral Imager for the Coastal Ocean (HICO)

<http://hico.coas.oregonstate.edu/>; <http://oceancolor.gsfc.nasa.gov/cms/data/hico>

- Partnership with U.S. Naval Research Lab, Office of Naval Research, Oregon State University, and NASA
- Active 2009 – 2014 aboard the International Space Station (ISS)
- 380 nm to 960 nm at 5.7 nm spectral resolution
- 90 m² spatial resolution
- Targeted data collection

Davis, C. O. (n.d.). *The Hyperspectral Imager for the Coastal Ocean (HICO): Sensor and Data Processing Overview* [PDF]. International Ocean Colour Coordinating Group.

<http://pace.gsfc.nasa.gov/>

An aerial photograph of a coastal region. On the left, a river with a complex delta system flows into a body of water. The land is green with some brown patches, possibly indicating different vegetation or soil types. The water transitions from a light turquoise near the shore to a deep blue further out. A large, semi-transparent white rectangular box is overlaid on the right side of the image, containing the text "Image 'Correction'" and a horizontal line.

Image "Correction"

Remote Sensing of Water Bodies

Atmospheric Correction

$$L_t(\lambda) = L_r(\lambda) + L_a(\lambda) + L_{ra}(\lambda) + T(\lambda, \theta)L_g(\lambda) + t(\lambda, \theta)L_{wc}(\lambda) + t(\lambda, \theta)L_w(\lambda)$$

>90%

<10%

Water-leaving radiance

$$R_{rs}(\lambda, 0^+) = \frac{L_w(\lambda)}{E_d(\lambda, 0^+)}$$

Downwelling Irradiance

Atmospheric Correction

$$L_t(\lambda) = L_r(\lambda) + L_a(\lambda) + L_{ra}(\lambda) + T(\lambda, \theta)L_g(\lambda) + t(\lambda, \theta)L_{wc}(\lambda) + t(\lambda, \theta)L_w(\lambda)$$

>90%

<10%

Atmospheric
correction

A satellite image of a coastal region, likely a river delta, showing a mix of green land, brownish water, and blue ocean. A semi-transparent light gray rectangular box is overlaid on the right side of the image, containing the title text.

Satellite Data Processing Levels

Levels of Data Processing

<http://oceancolor.gsfc.nasa.gov/cms/products>

- Level 0: unprocessed instrument data at full resolution, rawest format available
- Level 1A: reconstructed and unprocessed instrument data at full resolution
- Level 1B: L1A data with instrument/radiometric calibrations applied
- Level 2: Derived geophysical variables at same resolution as L1 data
- Level 3: L2 projected onto a well defined spatial grid over a well-defined time period
- Level 4: model output or results from analyses of lower level data
 - e.g., Primary Productivity

Data Processing Levels

L0: Raw instrument data

L1: Geolocated and calibrated

L2: Products derived from L1B

L3: Gridded and quality controlled

L4: Model output: derived variables

Harder to Use

Easier to Use

An aerial photograph of a coastal region. On the left, a river with a light-colored, silty delta flows into the sea. The coastline is irregular with small inlets and peninsulas. The water near the shore is a vibrant turquoise, transitioning to a deep blue further out. A semi-transparent light grey rectangle is overlaid on the right side of the image, containing the title text.

NASA Worldview

<https://worldview.earthdata.nasa.gov/>

- Interactive web-based tool for browsing satellite imagery
- Imagery is generally available within four hours of observation
- Daily imagery from May 2012 to present
- Data can be downloaded
- Image output in JPEG, PNG, GeoTIFF, and KML formats

NASA OceanColor Web – Data Access

<http://oceancolor.gsfc.nasa.gov/cms/dataaccess>

- Level 1 & 2 Browser
- Level 3 Browser
- Direct Data Access
- Data File Search
- SeaBASS Field Data

Data Access

The Ocean Biology Processing Group (OBPG) serves as the Distributed Active Archive Center (DAAC) for all Ocean Biology (OB) data produced or collected under NASA's Earth Observing System Data and Information System ([EOSDIS](#)). This website thus serves as the primary data access portal to the NASA OB.DAAC. The links below provide a variety of methods to access the holdings of the OB.DAAC, including visual browsers that enable point-and-click access by [data levels](#) and direct access for bulk download. In agreement with partner organizations, some data access requires [user registration](#) to enable better tracking of usage metrics.

Data Management

The data management plan describes the acquisition, generation, management, archive and distribution of science data products generated by the Ocean Data Processing System (ODPS). For a detailed description of science data products, data flows, supported sensors, and data availability, archiving and distribution, please refer to the [plan document](#).

Data Access Tools

[Level 1 & 2 Browser](#) - visual browse, download and data order access to all supported satellite data for Level-1 and Level-2 scenes at observed geographic scale and temporal granularity including cross satellite and *in situ* data search capabilities.

[Level 3 Browser](#) - visual access to global composites at various spatial and temporal scales.

[Direct Data Access](#) - direct access to all available data through http protocols suitable for [bulk download](#).

[Data File Search](#) - direct access via filename search, including support for wildcard search on partail filenames.

[SeaBASS Field Data](#) - community archive of field data relevant to ocean color research, algorithm development, and validation.

[Other Resources](#) - links to partners that also distribute OB.DAAC products or other products derived from OB.DAAC holdings.

SeaDAS

General Description

SeaDAS is a comprehensive image analysis package for the processing, display, analysis, and quality control of ocean color data. While originally developed to support the SeaWiFS mission, it now supports most US and international ocean color missions. The primary focus of SeaDAS is ocean color data, but it is applicable to many satellite-based earth science data analyses.

The latest version (SeaDAS 7.3.1) is the result of a collaboration with the developers of ESA's **BEAM** software package. The core visualization package for SeaDAS 7 is based on the BEAM framework, with extensions that provide the functionality provided by previous versions of SeaDAS..

- SeaDAS version 6.4
- MODISL1DB 1.8

Online Tutorials and Webinars for SeaDAS

<http://seadas.gsfc.nasa.gov/tutorial/>

- Strongly recommend completing all of the on-demand tutorials listed on this webpage
- SeaDAS supports a wide variety of satellite sensors so your investment in learning it will be time well spent
- Check out this SeaDAS webinar from June 15, 2016:
 - <https://earthdata.nasa.gov/user-resources/webinars-and-tutorials>

The screenshot displays the SeaDAS website interface. At the top, there is a header with a satellite image of the ocean and the text "OceanColor SeaDAS". Below the header is a navigation bar with links: Missions, Data, Documents, Analyses, People, Forum, Services, and Links. The main content area is titled "Video Tutorials and Demos" and includes a sorting instruction: "Sorted by recommended viewing order. Core videos first, then multi-tool case studies. Everything else follows in chronological order by release date." There are three video entries listed:

FOREWORD

The work reported herein has been sponsored by the Spacecraft Oceanography Project, NAVOCEANO, Washington, D. C. and carried out by the Willow Run Laboratories, a unit of the The University of Michigan's Institute of Science and Technology in Ann Arbor, under the direction of Marvin R. Holter, Head, Infrared and Optics Laboratory. Mr. John Sherman III is manager of the SPOC Project and provided technical monitoring of the investigation.

This document is the second annual report prepared under contract No. N62306-67-C-0243. These studies are to be continued under NASA sponsorship under contract NAS-9-9784. The Willow Run Laboratories' number for this report is 8973-26-F.

This report is one of a series in a program of remote sensing research initiated by M. R. Holter. A list of related reports in this program follows on succeeding pages.

WILLOW RUN LABORATORIES

ABSTRACT

✓e This study demonstrates successful remote determination of shallow water depth by measuring wave refraction changes and using the Fourier transform plane for wavelength measurements with data obtained at a Lake Michigan test site. The study shows that the technique is suitable for use from spacecraft altitudes, provided that water waves of suitable length occur in the region of interest. () R

A second demonstration of remote measurement of water depth was performed using data collected at Caesar Creek in the Florida Keys. For the first time, a newly developed multispectral technique, based on a ratio of reflected radiation in at least two spectral bands in the visible region of the spectrum, was used to determine water depth. Data were collected with The University of Michigan's multispectral scanner and recorded on magnetic tape. By digitizing the data and correcting for surface reflections, a depth chart can be generated from computer output.

An analysis of laser systems suitable for water depth determinations is also provided. It is anticipated that the use of laser depth measurements with the multispectral computer printout will provide best accuracy.

THE MEASUREMENT OF WATER DEPTH BY REMOTE SENSING TECHNIQUES

¹ INTRODUCTION

In a previous study (Ref.1), four variables were identified on which a remote sensor might operate in order to measure depth or deduce the location of shallower water. The four variables included temperature changes, color changes, wave refraction, and time differences for laser pulse reflections. As in all detection problems, a classification of a particular depth is more reliable if it depends on a convergence of evidence from several sensors.

Since it was found that temperature changes were useful for locating shallow water out not for measuring depth, this report concentrates on the use of the latter three variables for depth measurements performed in three ways.

(1) By measuring wave refraction effects in the Fourier transform domain produced by an optical processor, with an aerial photograph used as the input transparency. This technique, discussed in Section 2, lends itself to use from any altitude, including those of earth satellites, and is independent of the light transmission characteristics of water.

(2) By measuring at different spectral intervals the relative intensities of light reflected by the ocean or lake bottom and correcting for surface reflection and scattering, using a multi-spectral scanner such as that developed by The University of Michigan. The first depth measurements made by these techniques are reported in Section 3.

(3) By measuring the time difference of laser pulses reflected from the water surface and from the bottom. This technique (see Section 4) provides an independent measure of the water depth at sample locations.

It is the ultimate goal of this project to combine the latter two techniques: laser depth measurement taken along transects, with two-dimensional depth contours produced with the multi-spectral digital-processing technique described in this report. The result will be a system of making rapid surveys of near-shore environments or other regions about which knowledge of water depth is needed to reduce hazards to ship navigation, to aid marine engineering projects, to study shore erosion, to permit quick assessment of storm-induced changes, and to aid in investigation of lake level and estuarine problems.

Although this is the second annual report to be prepared under Contract N62306-67-C-0243, the study is not yet complete; it will be continued under NASA sponsorship (Contract NAS-9-9784).

WAVE ANALYSIS TECHNIQUES

Optical data-processing techniques can be adapted to measure water depth by analyzing the characteristics of water waves as recorded by aerial or space photography. It is known that shoal areas and beaches influence both the wavelength and the direction of waves passing over them. The forward velocity of a wave train decreases appreciably when the waves pass over an area in which the water depth is less than about half the wavelength. In addition to noting the change in typical wavelength directly on the original photograph, the change could be observed in other ways. An indirect effect of shoal areas and beaches is to increase the wave height, producing breakers; thus, breakers are another indication of shallow water. Another effect is to cause refraction of the wave, resulting in a change in azimuth of the wavefront and a corresponding change in the direction of wave advance.

The change in wavelength and in wavefront orientation can be observed by subjecting the original images to certain optical data-processing methods (Ref. 2). When a portion of the original image is illuminated by coherent light, such as that produced by a laser, and the transmitted light is focused by the use of a spherical lens, the resulting presentation on a screen at the focal point of the lens shows, in a polar coordinate frame, the distribution of both wavelength and wavefront orientation contained in the illuminated portion of the original image. It should, therefore, be possible to analyze aerial photography of sea surfaces both to detect shoal areas initially and to measure water depth in these areas.

2.1. METHODS OF DEPTH MEASUREMENT USING WAVE ANALYSIS

Several computational procedures can be used in estimating water depth from measurements of aerial photography. The analytical basis for these various procedures is discussed in this section, and experimental studies of individual procedures are presented in Section 2.3.

First order theory of wave swells describes a train of waves advancing through deep water as having a velocity related to its wavelength and wave period as in the following equations:

$$L_o = 5.12 T^2 \quad (1)$$

$$C_o = \frac{L_o}{T} = 5.12 T \quad (2)$$

where L_o = deep-water wavelength (ft)

C_o = deep-water wave velocity (fps)

T = wave period (sec)

As waves approach shallow water of depth, d , the velocity of wave advance, C , and the wavelength, L , decrease appreciably for values of d/L_o less than about 0.5.

WILLOW RUN LABORATORIES

This change in wave velocity is related to the fact that in shallow water the motion of individual particles of water is modified. In deep water, the orbit of each particle of water is circular in shape, with the radius of the circle decreasing rapidly with depth. In shallow water, the closeness of the bottom modifies the orbit to elliptical form, which has an effect on the forward velocity.

Since the period of a given wave train remains constant at all points along its path, a changing forward velocity changes the wavelength. It is therefore possible to measure depth from aerial photography by first measuring wave separation and directions of waves both in the shoal areas and in deep areas (deep is defined relative to the wavelength of the incoming waves). The wavelength in deep water (L_0) and the wavelength in shallow water (L) can be measured in a single aerial photograph. The measured ratio of wavelengths, L/L_0 , is functionally related to the ratio d/L_0 , so that depth, d , can be determined (Ref. 3). The optical data-processing methods discussed in the following sections provide an effective means of measuring L and L_0 .

When waves approach a beach at an angle, changes in the velocity of wave advance lead to changes in the wave orientation caused by refractive effects. The change in direction from deep to shallow water can also be accurately measured by optical data-processing methods. This approach is applicable, for example, for straight beaches with parallel contours. The direction of the incoming wave and the direction of the wave at the point of depth measurement are observed. These two measurements determine the ratio of depth, d , to deep water wavelength, L_0 . If L_0 is also measured, the depth can be determined. However, the measurement of changes in wave direction to determine depth presents complications. Where the bottom contour cannot be assumed as straight, the method must be modified by preparing a refraction diagram of the area of interest, extending into the ocean to points where the depth is equal to at least half the observed wavelength. As a means of detecting shoal areas, as distinguished from measuring them, the measurement of wave direction changes can be effective, provided the orientation of incoming waves is sufficiently regular to avoid masking the effect of the shoals.

Other approaches to depth measurement can be used if successive photographs at short intervals can be provided. Under these conditions, it becomes possible to measure not only wavelength and wave direction, but also wave velocity and wave period. If two pictures are taken at a known interval of time, the wave velocity in deep water, C_0 , and in the test area, C , can be determined. (To make accurate measurement of wave advance over a short time interval, a fixed reference point must be apparent in each photograph.) The wave velocity can be computed, by noting the change in wave position, as the ratio of distance traveled by the wave to the time interval between observations. The ratio C/C_0 derived from these pictures is equal to the ratio L/L_0 and can thus be used to determine d/L_0 . Wavelength can be measured directly from the photograph.

WILLOW RUN LABORATORIES

Another alternative would be to measure L and C in the shoal area only. Wave period, T , can be computed as the ratio of wavelength to wave velocity, L/C . The wave period remains constant as the wave travels from deep to shallow water; hence, the measurement of T provides a means of computing L_0 or C_0 by the use of Eqs. (1) or (2). This method thus requires measurements only in the test area and eliminates the need for measurements in deep water. Its accuracy depends on the regularity of the wave patterns present at the time of measurement and on the resolution of the photography.

2.2. APPLICATION OF FOURIER TRANSFORM PROCESSING

Optical data processing has been performed on a number of aerial photographs covering both open sea and shoal areas, such as beaches and reefs. A generally valid relationship has been found between the wave characteristics as measured from the aerial photograph and the wavelength and orientation characteristics recorded by the optical processor. If a swell or local wave pattern with a clearly defined orientation and predominant wavelength content is apparent on the aerial photograph, the Fourier transform pattern produced by the optical processor will tend to show this dominant wave pattern as a circular dot of finite size at the appropriate wavelength and angle. Distance of the dot from the center of the pattern is inversely proportional to wavelength. The finite size of the dot indicates a scatter, in both wavelength and direction in the original imagery, to be expected in wave patterns, even under favorable conditions. The irregularity of the fundamental pattern and the existence of local chop will tend to introduce both lower and higher frequency components into the Fourier transform. In many cases, therefore, the idealized dot pattern expected for a single sinusoidal wave component becomes elongated to include a considerable variation of wavelength components. The angular spread is less affected, so that, in many examples, wave direction may be determined more accurately than the wavelength itself.

The interrelation of sun elevation, view angle, and wave spectrum appears to have some effect on the transform representation of a particular area. The wave pattern is most visible at the edges of the sun-glitter pattern, and may be nearly invisible at the center of the pattern or far outside the pattern. Sun glitter seems to emphasize those wave crests which are tangent to the sun-glitter circle. If further study confirms this effect, it may be used to advantage in eliminating the confusion resulting from the existence of several wave patterns.

The conclusions reached so far are that the two-dimensional Fourier transform gives a useful indication of dominant wavelength and direction. To obtain accurate measurements, (1) the wave pattern must be a fairly regular one and not a confused combination of several different wave trains; and (2) the proper exposure and sun-glitter pattern must be used. It is believed that additional investigation will improve the definition of the best conditions of use and develop refinements in technique which would further increase the accuracy of determining wavelength and wave direction.

WILLOW RUN LABORATORIES

2.3. EXAMPLES OF OPTICAL DATA-PROCESSING TECHNIQUES FOR MEASURING DEPTH

As a quantitative example of the use of several wave analysis techniques for measuring water depth, an aerial photograph taken near the exit of the Grand River into Lake Michigan near Grand Haven was used. (See Figs. 1 and 2.) The objective of the task was to determine the depth of water in two areas, A and B. Area A is a rectangular area, 500×1300 ft, parallel to the shoreline, with its near edge about 270 ft offshore. Area B is a rectangular area of the same dimensions and orientation but with its near edge about 1600 ft offshore. To determine deep-water wavelength, L_0 , wave measurements were also made over Area C. The depth of water in Area C, approximately 40-45 ft, did not have an appreciable effect on the length or direction of the waves passing over it at the time the photograph was taken.

Two methods of calculation were used, one based on the difference in wavelength in Area A and Area C, and the other based on the change in direction of the waves in these two areas. Measurements of wavelength and wave direction were each made in more than one way to compare various techniques available.

We will consider first the determination of water depth by wavelength measurement. Measurements of wavelength were scaled directly from the aerial photograph and were also obtained from a Fourier transform made by optical processing (Fig. 3). The results of these measurements are shown in Table 1. Using the data taken from the Fourier transform measure-

FIGURE 1. LAKE MICHIGAN SHORELINE AT GRAND HAVEN

WILLOW RUN LABORATORIES

FIGURE 2. LAKE SURVEY CHART —GRAND HAVEN, MICHIGAN

TABLE 1. WAVELENGTHS DETERMINED BY
TWO METHODS

Method	Area A	Area B	Area C
Direct measurement of aerial photograph	53	82	92
Fourier transform	56.5	70	80

ments, the depth of Area A was found to be 7.9 ft. Inspection of Lake Survey Chart Number 765 of the Michigan coastline at Grand Haven indicates that the depth of Area A ranges from 6 to 10 ft. Fourier transform measurements were also used to compute the depth of Area B. The computed depth was 15 ft; depths determined from the chart ranged from 14 to 18 ft.

Water depth in Area A was also computed by comparing the angle of the incoming wave in Area A with that of Area C, where the wave orientation was presumably still outside the influence of the shore. Angle measurements were made by reference to both the original photograph and the Fourier transform.

Both methods gave values of 60° for Area C and 35° for Area A, measured with respect to the shoreline. Using these values, the value of d/L_0 for Area A can be obtained by using data

FIGURE 3. DIFFRACTIVE OPTICAL SYSTEM

such as that published in Ref. [4]. The value obtained for d/L_0 was found to be 0.086, and using the wavelength of 80 ft from Table 1, the water depth in Area A is computed as 6.9 ft, which checks closely with the value determined by wavelength measurements. For Area B, the angle of approach was 45° , giving an estimated depth of 12.0 ft. This is appreciably less than the chart value of 14-18 ft.

2.4. EFFECT OF ALTITUDE AND CLOUD COVER

The data from Mission 72, Lake Michigan, together with data from Mission 79, Gulf of Mexico, and samples of satellite photography provided an initial data base to study the effect of increasing altitude and cloud cover on the generation of interpretable optical transforms and on the measurement of wavelength. One of the advantages in using the optical transform is that at smaller photographic scales, the dot separation from the center in the transform increases and less confusion results in the bright central portion of the transform pattern. Figure 4, taken from an area near Cayo Arenas in the Gulf of Mexico, illustrates this effect. The area is in open deep water away from the diffraction effects caused by the island or refraction effects due to submerged shoals. The photography was taken at an altitude of 22,000 ft with a 6-in. focal length lens. Note the clean separation of the dot pattern for the fundamental wave component

FIGURE 4. CAYO ARENAS—(GULF OF MEXICO)

of the sea surface (see Figure 5). Figure 6 shows the transforms taken nearer the island at three different locations; the azimuthal changes in wave direction due to the diffraction of waves around the island are shown clearly in the transform domain when compared to the transform in Fig. 5.

The wavelengths measured in the sun-glitter region in Fig. 6 were in the 100-ft range but no depth measurements were made in the area since depths of 50 ft or less were not present. The required ratio of depth to wavelength of less than one-half implies that a determination of depth in a given area will depend on the existence of a particular set of conditions at the time the data is taken. Since these conditions may not always exist, a technique is needed to analyze rapidly many photographs in which routine data has been taken for a variety of other purposes. It is expected that scanning the transform plane for the dot separation will be a quicker and simpler method than scanning the original photograph.

Additional tests were also made of the effects of cloud patterns in portions of the photograph. Figure 7 shows a comparison of two transforms taken from sections of the photograph with and without cloud obscuration. The fundamental wavelength component was observed in both cases. The large cloud pattern generally transforms into the lower spatial frequencies located near the center. The presence of scattered clouds does effect the overall exposure

WILLOW RUN LABORATORIES

(a) Aerial Photograph

(b) Fourier Transform

FIGURE 5. WAVES IN OPEN WATER

during the construction of the optical transform, indicating that an increase in exposure time may be necessary in some cases.

2.5. SPACE PHOTOGRAPHY

Frame AS7-4-1607 taken during the Apollo 7 flight distinctly shows a widespread, long wavelength swell moving in the direction of the Schouten Islands near New Guinea. The swell has an extremely regular pattern, consisting of wave crests many miles in length, essentially straight, with little or no apparent variation in wavelength. This type of wave pattern would have been caused by a recent storm at a considerable distance; the dispersive characteristic of water waves has separated the wavelength components in the storm area, so that only a single wavelength is present in the picture.

Optical data processing was applied to one section of this picture in which the wave pattern was most distinct (Fig. 8a). The resulting transform shows a very definite wave component ranging from 1040 to 1220 ft and an orientation angle ranging from 40 to 50°. Corresponding to the figures derived from the transform, measurements made from the original image indicated a typical wavelength of 1100-1200 ft and an orientation angle of 45°. An analysis of this frame has also been performed by Noble (Ref. 5).

WILLOW RUN LABORATORIES

(a) Aerial Photograph (West of Cayo Arenas)

(b) Fourier Transform

FIGURE 6. DIFFRACTION OF WATER WAVES

The swell can be seen reaching the large island shown in the picture, but because the sun-glitter pattern in the vicinity of the island provides only a low contrast in the wave image, it is difficult to obtain a transform pattern in this region. Measurements taken from the original image indicate that the wavelength becomes shorter in the vicinity of the island, but the wave direction does not appear to change appreciably. The long wavelengths composing the swell would be sensitive to relatively great bottom depths and are thus most likely to provide useful information concerning shallow water. It would be highly desirable to obtain imagery of long swells approaching land at shorter intervals between frames so that every part of the water surface of interest is in the favorable part of the sun-glitter pattern on at least one exposure.

Frame AS6-2-918 of Apollo 6 imagery shows an extensive wave system covering large areas of open ocean. The transform taken over a part of the frame (see Fig. 8b) representing a rectangle many miles on a side shows a wave system consisting predominantly of wavelengths ranging from 850 to 1050 ft over an angular range of 20° . Typical measurements from the original image show a wavelength of 1020 ft at an angle in the exact center of the angular range. If wave patterns with the easily identifiable limits shown in this example were available in the

WILLOW RUN LABORATORIES

(a) Aerial Photograph

(b) Fourier Transform

FIGURE 7. CLOUDS AND CLOUD SHADOWS

neighborhood of islands of shallow areas, it should be possible to detect and measure shallow water with fair accuracy.

Measurements were made from Fourier transforms taken of Apollo frame AS7-4-1607 and AS6-2-918 in order to determine the precision of wavelength and angle measurements produced by optical data-processing techniques, using manual data reduction by scale and protractor. Frame AS7-4-1607 is distinguished by the fact that the wave system is very regular as to both wavelength and wave orientation. The results of optical data processing on this frame indicate that wavelength measurements can be obtained with a precision of 2 or 3% and angle measurements with a precision of 2 or 3°. Assuming that this precision could be obtained in measuring both L and L_0 , it is possible to estimate the accuracy of computing depth for a known value of d/L_0 . If d/L_0 is equal to 0.100, for example, the depth could be estimated within about $\pm 10\%$. (In the Lake Michigan example previously presented, Area A had a d/L_0 of about 0.100.)

FIGURE 8. OPTICAL DATA PROCESSING

2.6. ALTERNATIVE METHODS OF OPTICAL DATA PROCESSING

2.6.1. TWO-DIMENSIONAL CROSS-CORRELATION PROCESSING

Other optical data-processing approaches to the problem of detecting and measuring shoal areas were investigated during this project to determine their potential advantages compared to the use of two-dimensional Fourier transform approach. For example, a two-dimensional cross correlation of the sea-surface image would contain information similar to that contained in the Fourier transform, but would have the advantage that the scale of output presentation is not tied as rigidly to the scale of the original image transparency placed in the optical data-processing system. It is possible, therefore, that relatively small sea-surface areas at relatively large scales could be used for processing. This would improve the spatial resolution with which wave data could be processed, although it would not reduce the scatter in the wave data.

As a typical example of results obtainable by this method, a cross-correlation display was made of a portion of Frame 8402 taken of Lake Michigan beach which contains a linear wave pattern approaching the beach. (See Fig. 9 for the input transparency made from the photograph.) This wave pattern is oriented at an angle of approximately 20° . The output produced by taking the cross-correlation of Fig. 9 is a broad band, oriented at approximately the same angle, representing the high correlation of the light-reflectance pattern along the wave crest. This broad band is bound on either side by two parallel dark bands representing the difference in reflectance between the wave crest and the adjacent wave troughs. The separation between the centers of the dark bands, produced at a scale of 7.4 times the scale of the original image, corresponds to the dominant wavelength in the image. Thus, the cross-correlation diagram can show the orientation and wavelength of a well defined wave pattern. The diagram can be adjusted for use with a broad range of photographic scale factors and can be restricted to coverage of small sea-surface areas. However, it seems to be more difficult to set up and work with, and more difficult to interpret than the Fourier transform, particularly if several wave trains are present at the same time. Although its use should not be ruled out on the basis of the brief investigation made so far, the present study has been concentrated on other methods.

2.6.2. SECTIONAL AUTOCORRELATION DIAGRAMS

Figure 10 is an example of a sectional autocorrelation diagram of a small area taken from Frame 1037 of the Lake Michigan shoreline. In this type of data analysis, the variable density pattern of a linear strip of the original photograph orthogonal to the wave crests is transformed into a corresponding linear strip on the autocorrelation diagram, the brightness of which corresponds to the autocorrelation of the signal on the original linear strip. (See Ref. 4.) The autocorrelation diagram along a vertical strip at any given value of x thus corresponds to the wave pattern along a vertical strip of the original image at a proportional distance along its x axis;

FIGURE 9. INPUT TRANSPARENCY FOR CROSS-CORRELATION OPERATION ON FRAME 8402—LAKE MICHIGAN BEACH

however, the scales are not necessarily equal on the two diagrams. The bright band near the center of the diagram corresponds to the peak value of the autocorrelation function for $\tau = 0$. In both directions from this bright band, the brightness varies with distance from the center, i.e., increasing magnitudes of τ , both positive and negative as distance from the center increases. The periodic character of the autocorrelation pattern indicates the presence of periodic variations in the original image, and the predominant wavelength in the original can be measured from the autocorrelation diagram, using a fixed scale factor determined by the optical setup. It should be noted that the sectional autocorrelation detects wavelength components only in one direction; components at right angles to this direction are not recorded.

The sectional autocorrelogram is useful in bringing out the predominant wavelength present in the original image. Where the original image has a regular pattern of waves, the perio-

FIGURE 10. SECTIONAL AUTOCORRELATION OF FRAME 1037

dicity present in the autocorrelation diagram is apparent for 5 or 6 cycles and the wavelength on this diagram is easy to measure. However, the extent of the periodicity and its wavelength vary substantially depending on the position of the strip along the x axis of the diagram, indicating the variability inherent in the original image. Nevertheless, this form of presentation makes it possible to detect the predominant wavelength more easily than with the two-dimensional transform. Measurement of wavelength could be adapted to automatic processing without great difficulty.

2.6.3. SYSTEM-OPERATING CONCEPT USING OPTICAL DATA PROCESSING

Assuming that the use of the Fourier transform procedure proves to be adequate for our purposes, the resulting system might operate in the following manner. We will consider first the problem of detecting a shoal area in open water, where the shoal area and depth have sufficient effect to produce an appreciable refraction of the waves, causing a change in direction of at least 10° . Assuming the use of a satellite, imagery would be collected by means of a television system having sufficient resolution to see waves as short as 50 or 100 ft in wavelength. The television system would be continuously aimed toward the edge of the sun-glitter pattern, and imagery would be collected in such a manner as to observe the same portion of the sun-glitter pattern while the satellite traverses distances of many miles. This method of observation would assure uniformity in treatment of the wave patterns in the recording and processing operations. (The best angle of sun elevation for observing waves still remains to be determined.)

WILLOW RUN LABORATORIES

The resulting image would be placed in an optical processing system designed to scan the image using an aperture as small as practicable. It is assumed that this aperture would project an area through the system which at any instant contained perhaps ten or twenty wave crests. In addition to a recording camera, the optical processing system would include a photoelectric device capable of producing a direct measurement of the total spread and mean value of angular orientation of the primary pattern in the transform. By restricting the data collection to sea conditions which consist of regular wave patterns (straight-line, long-crested swells) with no major interfering wave trains crossing the main pattern at small intersecting angles, it would be possible to restrict the normal transform to easily predictable patterns. Any anomalous variations from the normal range of orientations would then be easy to detect and could be checked further to assure that it was produced by shoals.

We will next consider the problem of measuring the spatial extent and depth of a shoal area, the existence of which has already been detected by other means. Here again it is important to restrict the coverage to conditions in which the sun-glitter pattern is uniform over the entire area of interest and in which the incoming wave pattern is as uniform as possible. This latter requirement would be realized under conditions of calm local seas in which an incoming swell arrives from a direction that minimizes interfering patterns caused by reflection or diffraction. Ocean forecasts could be used to select periods of conditions favorable for data acquisition. If the minimum usable aperture were small enough to resolve changes in wavefront alignment over short distances, and if the automatic photoelectric recording system mentioned previously were used, it would be possible to compute and plot the orthogonal to the wavefront as a function of location on the image. If a series of continuous orthogonals could be produced in this manner, and the incoming wave velocity were known, the orthogonals could conceivably be used to compute the depth of the bottom as a function of location. The accuracy with which this can be done cannot be predicted in advance, but would have to be determined by experiment. It would be possible to carry out such an experiment by hand calculation for one or two cases to determine the feasibility of the method.

In these data-processing operations, some human monitoring would be required to pre-select usable photographs and pinpoint areas of interest, but automatic processing equipment would perform the detailed analysis of the photographs.

Using a method of wavelength measurement, the data-processing operation would consist of scanning those parts of the picture which are of interest. Deep-water areas designated by the operator would be processed to provide measurements of L_0 . Large areas of deep water could be scanned to provide a large sample for determining mean wavelength. Scanning of shallow areas, on the other hand, must be limited to small apertures in order to maintain fine resolution in measurement of these areas. Readout of the processor would give a mean wavelength directly. Using analog or digital processing, the wavelength at each point over shoal areas could be computed as a fraction of deep-water wavelength, and water depth of the particular point computed.

WILLOW RUN LABORATORIES

2.6.4. WAVE VELOCITY MEASUREMENTS

2.6.4.1. Moving Picture Techniques

Preliminary exploratory studies were conducted to determine the usefulness of moving pictures (or long sequences of still pictures) for measuring wave velocities, as a means of determining water depth. It appears that this technique can be used successfully, provided the pictures are taken under appropriate conditions.

It is desirable to obtain a picture sequence covering an interval of time sufficient to observe a single wave or short train of waves moving from deep water to shallow water. Obviously, the total period of time during which a small area could be kept under surveillance would be greatest if a helicopter were used as an aerial platform. If a fixed-wing aircraft is used, however, there is a definite limit for surveillance time determined by the aircraft speed and altitude, and the camera characteristics.

Assume an aircraft flying at an altitude of 20,000 ft and a speed of 250 knots (420 fps). Although the use of a moving picture camera is suggested here, even better results might be obtained with a camera designed to obtain wide-angle, high-resolution pictures at intervals of $1/2$ to 1 sec. If the camera has a field of view of 74° , a single frame would cover a distance of 30,000 ft on the earth's surface. A small area would thus remain in view of the camera for a period of 72 sec, although it is not likely that the illumination conditions for observing waves would be suitable over the entire range of viewing angles. In 72 sec, a wave train of 100-ft wavelength, travelling at a speed of about 23 fps, would move a distance of 1600 ft in deep water or 1100 ft in 10-ft-deep water. These distances are sufficient in many locations to track the wave from deep to shallow water. If longer wavelengths are present, they can be tracked over even greater distances.

With a resolution of 30 lines/mm and a 70-mm frame size, the ground resolution would be about 10 ft. Image motion would not appreciably degrade this resolution, provided the exposure could be kept to $1/125$ sec.

If 10-ft-deep water is to be measured by observing 100-ft waves, it would be desirable to measure wave velocity with no more than a 10% error. Even with 10-ft ground resolution, it should be possible to estimate the center of a wave crest to 10 ft. Thus, a 100-ft wave advance is needed to obtain the necessary measurement accuracy. In 10-ft-deep water, measurement accuracy requires a time interval of about 6 sec between the frames used for measurement of wave advance.

A representative system adapted to satellite application might be a television camera with a 2-in. screen having a total resolution of 5000 lines/frame and an optical system with a 12-in focal length. From an altitude of 300 nautical miles, this camera would produce a ground resolution of 60 ft and a viewing time of 13 sec. Obviously, this system would be less accurate

WILLOW RUN LABORATORIES

than the aircraft system previously described, but could be used to observe longer wavelengths. For example, this system would allow observation of a wavelength of 500 ft corresponding to a wave velocity of 50 fps travelling 650 ft, in the available viewing time.

2.6.4.2. Experiments with Motion Pictures of Waves

Wave motions were observed by means of 16-mm moving pictures taken in a flight over the eastern shoreline of Lake Michigan and from a bridge over Ford Lake. The purpose of this exploratory study was to determine the usefulness of moving pictures for measuring wave velocities and directions as a basis for determining water depth. Although the aircraft flight characteristics were not optimum for the purpose, interesting and useful results were obtained.

The pictures of the Lake Michigan shoreline show incoming waves approaching the beaches. The height and speed of the airplane were such that single waves remained in the field of view of the camera for only 3 or 4 sec. With the limited observation period available, it was not possible to follow the progress of a single wave long enough to determine its velocity with adequate accuracy. An aerial platform with a lower velocity-height ratio would therefore be advantageous for extending the period of time for observing individual waves. Individual waves could then be identified and followed for the entire period of time they were in view, indicating that it would be possible to obtain accurate measurements of wave velocity over extended distances. In many instances, an individual wave crest appears to change shape and may disappear. However, wave trains of as few as two or three wave crests will maintain their identity and can be followed by the eye.

In order to obtain usable velocity measurements, a fixed object or landmark must be present in the scene, as a reference for distance measurements, and the photographic scale must be known either from measurements of known objects in the scene itself or from a knowledge of the aircraft altitude and camera characteristics.

The pictures taken from a bridge at Ford Lake were oblique views. They were not suitable for making velocity measurements, but covered longer intervals of time than were possible with aerial photography. The movies tended to confirm the conclusions previously stated about the ability to track individual waves and wave trains for substantial periods of time.

2.7. RECOMMENDATIONS FOR FUTURE RESEARCH AND DEVELOPMENT

The work performed under the present program indicates that methods of wave analysis using aerial and space photography and optical data-processing techniques for detection and measurement of doubtful shoals are technically feasible and offer the possibility of improved performance over existing methods. Much additional theoretical and experimental research remains to be done to develop these techniques to operational status. This section outlines some directions for future research to achieve an operational capability.

WILLOW RUN LABORATORIES

2.7.1. ACQUISITION OF ADDITIONAL PHOTOGRAPHIC COVERAGE

Analysis of aerial and space photography obtained during the present project suggests some of the requirements for obtaining useful data from such coverage. By obtaining photographic coverage meeting these specifications, it should be possible to demonstrate experimentally the capabilities indicated by analysis of imagery taken under unfavorable conditions.

Pictures should be taken with both 9-in. × 9-in. aerial camera and 16- or 35-mm movie camera. Pictures of selected areas should be taken simultaneously with both types of cameras to provide comparison of results. It is preferable to take a large number of pictures of a small number of selected areas (including both beaches and open ocean) rather than single pictures at evenly spaced intervals of 10-20 sec. Pictures of beach areas should be taken from a position that produces sun glitter all the way to the shore line. (In the Lake Michigan pictures, the sun glitter was concentrated at some distance offshore, so that breakers and surf did not show up very well.)

One or more sets of pictures should be taken of areas covered by ground-truth teams. Ground truth should be collected simultaneously with the flyover. Features to observe include dominant period of breakers and character of chop, swell, and other wave components (e.g., size, orientation, and wavelength). If convenient, still pictures or movies of the offshore area should be taken. Depth measurements at points offshore should be obtained in as much detail as possible, with distances recorded offshore and alongshore from identifiable landmarks.

2.7.1.1. Aerial Camera

For each sequence of pictures, intervals between shots should be 1 to 3 sec, depending on how rapidly film can be advanced. The interval should be known to 0.1 sec or better to allow computation of speed of wave advance. An intervalometer should be used, if available. A stop watch placed at the edge of the camera frame would provide necessary accuracy.

If a 6-in. focal length camera is used (74° field of view), the frame covers a square area on the ground of 30,000 ft on a side (for 20,000-ft flight altitude). This area would stay within view for about 70 sec (at 250-knot speed), but variations in the sun-glitter pattern might limit the usable time to much less.

2.7.1.2. Moving Pictures

Color film should be used throughout the tests, since it increases the ability to discriminate detail. Pictures should be taken with the camera mounted in the aircraft for vertical photography. Camera speeds of 16 frames/sec are adequate to follow wave trains. For aircraft applications, film speed and lens opening should be chosen to permit the use of exposure as short as $1/125$ sec, in order to avoid appreciable loss of resolution because of image motion. Neglecting image motion, ground resolution for a 16-mm camera at 30 1/mm from 20,000 ft would be about 25 ft.

WILLOW RUN LABORATORIES

2.7.1.3. Choice of Subject Matter

For experimental studies, ocean areas used as subjects for data collection should preferably be in the neighborhood of islands or other land masses which should appear in the imagery as convenient reference points. Areas for which there is extensive hydrographic data are desirable, although ground-truth data may be needed in addition to check some of the results. Some areas in which doubtful hydrographic data exist should also be included to provide checks on the effectiveness of the methods being developed.

Timing of coverage is as important as selection of subject areas. Past experience indicates the importance of making measurements on regular wave trains, on which there is as little interference as possible from other wave trains. Minimum interference from cloud cover is also desirable. Scheduling flights during weather conditions conducive to obtaining useful coverage should be aided by information obtained from weather- and ocean-forecasting services.

2.7.2. PROPOSED SPACE EXPERIMENT IN OCEANOGRAPHY

Experiments conducted with satellite-based, remote sensing equipment would permit further evaluation of the techniques under realistic operational conditions. In these experiments, imagery should be obtained of ocean areas known to contain shallow bottoms, e.g., areas in the Bahamas. Repeated coverage should be obtained during succeeding passes over the same test area. Preferably, coverage should be obtained under various conditions of sun elevation. It is particularly desirable to obtain coverage at times when extensive wave systems are present. Long wavelength swells arising from distant storms provide the best conditions for detecting and measuring shallow water.

Usefulness of the data would be enhanced if overlapping coverage could be obtained during a single pass. Since waves are most visible in the sun-glitter pattern, the overlapping coverage would increase the ocean area observed under conditions of best visibility. Also, if enough overlapping frames could be repeated at intervals as short as 1 sec, it might be possible to estimate wave velocities by observing the advance of individual waves.

3

MULTISPECTRAL PROCESSING TECHNIQUES FOR DEPTH MEASUREMENTS

3.1. INTRODUCTION

The shallow water features in the Caesar Creek and Pacific Reef regions off the coast of Miami, Florida, provide an ideal situation for verifying depth-measurement techniques. Caesar Creek is a ship channel which is easily recognizable in aerial imagery because of its shape and depth. The Pacific Reef has sufficient spatial variation to offer easy recognition as well as a

WILLOW RUN LABORATORIES

large variety of depths, making it useful for calibrating depth-measurement schemes. These areas are shown on the chart depicted in Fig. 11.

The availability of multispectral data for doing water-depth measurements suggests at least two techniques. One straightforward technique would be to compute spectral signatures for water of known depths in order to recognize areas of comparable depths elsewhere in the scene. Although this approach has been used successfully in recognizing surface features, the introduction of an intervening water layer—with its variable absorptance—over bottom types with variable reflectance would tend to make this approach ineffective.

The other technique, adopted for this study, overcomes this limitation; this approach utilizes a comparison of the intensities of light reflected from the ocean floor as determined by signal levels in different channels of a multispectral optical-mechanical scanner. The details of this approach are given in the following section. Because of the nature of the technique,

FIGURE 11. MULTISPECTRAL MAPPING OF CAESAR CREEK AND PACIFIC REEF.

WILLOW RUN LABORATORIES

variations in water absorptance and in the reflectance of the ocean floor tend to be damped out, allowing a fairly accurate depth determination over a wide area.

Because the water must be quite transparent in order to measure reflections from the ocean floor, it is only practical to use wavelengths close to $0.54 \mu\text{m}$. The fact that the configuration of existing multispectral scanners produces only three or four usable wavelength channels imposes a slight limitation on the approach. It will be shown, however, that depths can be determined accurately in spite of this limitation. Development of a scanner with high spectral resolution from about 0.5 to $0.64 \mu\text{m}$ would serve to improve the measurements and increase the reliability of detecting shoals.

3.2. APPROACH

The electromagnetic power received by an optical system oriented toward the water consists of components of scattered sunlight (from the water and the atmosphere) and reflected sunlight (from the ocean floor and the water surface). Because the power reflected by the ocean floor must pass through an absorbing water layer, the amount reaching the system will be dependent upon the amount of absorptance which, in turn, is a function of the thickness of the water layer.

Quantitatively, this situation can be described by the following simplified equation:

$$P = \rho H e^{-(\sec \theta + \sec \phi) \alpha z} + \rho_{a/w} H + P_{\text{scattered}} \quad (3)$$

where

- P = total power received
- $P_{\text{scattered}}$ = power scattered (all sources)
- H = solar irradiance at water surface
- ρ = reflectance of ocean floor
- $\rho_{a/w}$ = reflectance of air/water interface
- α = absorptance of the water
- z = depth of the water
- θ = viewing angle (from vertical)
- ϕ = solar illumination angle (from vertical)

Admittedly, this equation does not account for atmospheric absorption, differences in absorption and scattering in the light incident upon and reflected from the ocean floor, and other relatively minor effects. The inclusion of these effects, however, would greatly complicate matters without appreciably improving the accuracy of the measurements.

The equation, even in its present simple form, does not lend itself well to depth calculations because of the two terms listed last above. The elimination of these terms is accomplished by measuring P over deep water:

WILLOW RUN LABORATORIES

$$P_{\infty} = \lim_{z \rightarrow \infty} P = \rho_{a/w} H + P_{\text{scattered}} \quad (4)$$

It is not quite true that these terms are the same as those in Eq. (3), since the amount of light scattered by deep water is greater than that scattered by shallow water. The difference, however, will be small, and thus it should be possible to reduce the equation to a manageable form as follows:

$$P - P_{\infty} = \rho H e^{-(\sec \theta + \sec \phi) \alpha z} \quad (5)$$

In practice, this is accomplished by scanning over deep water and averaging together many scan lines for each spectral channel to obtain P_{∞} as a function of scan angle and wavelength. This function is then subtracted from each scan line obtained over shallow water, leaving, to first order, only the desired quantity represented by Eq. (5).

In actual applications, there are very few known quantities in Eq. (5). The power (P) is represented by a voltage (V_i) on magnetic tape, recorded from a sensor output:

$$V_i = K_i P_i \quad (6)$$

The constant, K_i , can be obtained from system calibration. In the Caesar Creek and Pacific Reef application, signals from the sensors were measured as the scanner passed over a piece of opal glass, through which sunlight was passing, at the end of each scan line. The voltage thus obtained from a given spectral channel can be represented by the following:

$$(V_s)_i = K_i (\rho_s)_i H_{\lambda i} \quad (7)$$

where s refers to the sun sensor, i refers to the channel of interest, and $(\rho_s)_i$ is the throughput of the sun sensor, determined by using standard reflectance panels on the ground. Thus, for example, if the reflectance of the scene were equal to ρ_s , the signal from the scene would have the same amplitude as the signal from the sun sensor. Since V_s and ρ_s are known, Eq. (7) can be inverted and substituted into (6) to obtain

$$V_i = \frac{(V_s)_i}{(\rho_s)_i} \frac{P_i}{H_{\lambda i}} \quad (8)$$

In turn, substitution of (8) into (5) yields

$$V_i = \frac{(V_s)_i}{(\rho_s)_i} \rho_i e^{-(\sec \theta + \sec \phi) \alpha_i z} \quad (9)$$

The expression thus obtained is in a form which can be used for depth measurements, since everything except z is either known or can be determined well enough in advance to provide reasonably accurate results.

WILLOW RUN LABORATORIES

The most troublesome quantities in Eq. (9) are ρ and α . Further manipulation of the equation can ameliorate the situation. Using two channels of data, and taking the ratio of the voltages, we obtain

$$\frac{V_i}{V_j} = \frac{(V_s)_i (\rho_s)_j \rho_i}{(\rho_s)_i (V_s)_j \rho_j} e^{-(\sec \theta + \sec \phi)(\alpha_i - \alpha_j)z} \quad (10)$$

Rearranging and solving for z , (10) becomes

$$z = \frac{1}{(\sec \theta + \sec \phi)(\alpha_i - \alpha_j)} \ln \frac{(V_i/\rho_i) (V_s/\rho_s)_i}{(V_j/\rho_j) (V_s/\rho_s)_j} \quad (11)$$

Note that we are now concerned with differences in α and ratios of ρ .

To assess the improvement thus obtained, consider Fig. 12 which shows α for several different water conditions. Note that there are two distinct regions where $\alpha_i - \alpha_j$ is independent of water conditions:

- (1) 0.55 μm to 0.64 μm
- (2) wavelengths above and below (1)

Region (1) encompasses three spectral channels of The University of Michigan scanner: 0.52-0.55 μm , 0.55-0.58 μm and 0.58-0.62 μm . Because these channels have high signal-to-noise ratios and are in the region of highest water transparency, they were used in the trial runs of the depth-measuring program.

A similar consideration applies in the case of the reflectance of the ocean floor. Curves of the reflectance (see Fig. 13) of some representative wet sands show that the ratio of the reflectances of two bottom types at a given wavelength is relatively insensitive to variations in the kind of materials present.

In order to eliminate areas which were not underwater, use was made of the 0.8- to 1.0- μm channel of the multispectral scanner. For all practical purposes, water is opaque in this near infrared channel. Therefore, any signal detected in this channel (after subtracting scattered sunlight and surface reflections) would indicate an above-water feature, making depth measurement impossible. Such points were assigned a depth of zero and calculations were begun on the next point in the scene.

Computer programs were devised to (1) measure the deep-water signal, (2) subtract this measurement from the data, and (3) compute the depth according to Eq. (11). This program can be used on weighting factors applied to the combinations of spectral channels with outputs of (1) the best combination, (2) a weighted mean, and (3) a weighted deviation. The format of the out-

WILLOW RUN LABORATORIES

puts is such that a computer map can be printed directly from them, as shown in Fig. 14.

[Note: This figure was obtained from data which had been smoothed in order to diminish the effects of system noise. In effect, the spatial resolution was diminished to an effective 20 ft × 20 ft, although each point on the computer map still represents a 6.7-ft × 6.7-ft area.]

FIGURE 14. DEPTH CHART — CAESAR CREEK — OBTAINED BY DIGITAL PROCESSING OF MULTISPECTRAL SCANNING (See enlargement of Fig. 14 inserted at the end of the report.)

3.3. ANALYSIS OF RESULTS

The depth map for the Caesar Creek area was compared with the U. S. Coast and Geodetic chart of the area in Fig. 10. The deepest portion of the ship channel, according to the computer output, is 1.25 m (i.e., about 4 ft). According to the chart, the actual depth goes up to 20 ft. In the absence of onsite verification of the true depth, the following explanations are offered:

- (1) The true depth is about 4 ft, because the channel has been filled in with silt.
- (2) The true depth is greater than 4 ft, but the water has become clouded (e.g., by tidal action).
- (3) The calculations are not as accurate as they should be.

Some hand calculations indicate that (3) is not a good explanation of this effect. Thus, we tend toward (1) or (2).

The calculations proceeded as follows. The data for spectral channel 4 (i.e., 0.52-0.55 μm) are, at the deepest point of the ship channel,

WILLOW RUN LABORATORIES

$$\begin{aligned}
 V_4 &= 0.371 \\
 \rho_4 &= \text{unknown} \\
 (V_s)_4 &= 1.60 \\
 (\rho_s)_4 &= 0.14 \\
 \alpha_4 &= 0.25 \text{ (mean coastal water)} m^{-1} \\
 \theta_4 &= 0.15 \text{ rad} \\
 \phi_4 &= 0.60 \text{ rad}
 \end{aligned}$$

Using an inverted form of Eq. (9) and using $z = 6$ m, we obtain:

$$\rho_4 = V_4 \left(\frac{\rho_s}{V_s} \right)_4 e^{(\sec \theta + \sec \phi) \alpha_4 z} = 0.78 \quad (12)$$

This figure is too high. Calculations for channels 5 and 6, the other two used, yield reflectances of 1.15 and 4.57 respectively. Of course, these are physically impossible. These figures appear to be at least 8 times greater than the true values of ρ , implying that z is probably at least 3 times too large. Using $z = 2$ m (about 6 1/2 ft), the computed values of ρ become:

$$\begin{aligned}
 \rho_4 &= 0.10 \\
 \rho_5 &= 0.15 \\
 \rho_6 &= 0.59
 \end{aligned}$$

These values are certainly more realistic.

Similar values for ρ could have been obtained had we used the mean oceanic value for α (i.e., $\alpha_4 = 0.083$, $\alpha_5 = 0.115$, and $\alpha_6 = 0.25$) and the chart-obtained value of $z = 6$ m:

$$\begin{aligned}
 \rho_4 &= 0.09 \\
 \rho_5 &= 0.14 \\
 \rho_6 &= 0.41
 \end{aligned}$$

Subsequent onsite verification showed that the high signals in this area were probably the result of very turbid water occurring at the time of high tide.

3.4. VARIABILITY IN THE DATA

There are at least three sources of variability of the data put out by the depth-measurement analysis: (1) system noise, including the analog-to-digital quantization of signal levels; (2) uncertainties and/or variations in the turbidity of the water and in the reflectance of the ocean floor; and (3) uncertainties and/or variations in the deep-water signal levels, including sun glint and wave phenomena. In addition to these factors, the equations which have been programmed are greatly simplified.

WILLOW RUN LABORATORIES

In the face of these observations, it is interesting to note that the measurements which have been obtained are in agreement with the charts of the area. Onsite inspections should remove uncertainties which still remain.

Aside from considerations of the accuracy of the results, there is the question of verification of the results when using different combinations of spectral channels. Several computer maps of the same area shown in Fig. 13 were made, comparing the results using different combinations of data channels 4, 5, and 6. Each combination was weighted by a normalized function proportional to the difference in absorptances of the pair of spectral channels being used. It was verified that the large difference in absorptances provides greater confidence in the calculations.

In future work on this problem, it is hoped that onsite depth measurements and/or the inclusion of a laser depth-measuring device will provide calibration of the technique.

4

LASER-RANGING TECHNIQUES FOR IDENTIFYING SHALLOW WATER FEATURES

An earlier study conducted under this program (see Ref. 1) concluded that water depth could be determined directly by use of an optical laser system which would measure the time difference between the laser-beam reflection from the water surface and the reflection from the bottom. Because of some ambiguities and errors in the discussion of this technique in Ref. [1], the discussion which follows is intended to supplement and update the previous annual report.

The performance of a laser-ranging system in depth measurements is dependent upon many variables, including spectral characteristics, geometric factors, and system design parameters. Further constraints are effected by size, weight, and power limitations imposed by the platform (i.e., the aircraft or satellite), as well as by the altitude and velocity of the platform.

Referring to the earlier study, the maximum depth of penetration of the laser beam in water can be expressed as follows:

$$r = \underbrace{\frac{1}{2\alpha}}_{\text{Term 1}} \ln \left\{ \underbrace{\rho_b \tau_a^2 (1 - \rho_w)^2}_{\text{Term 2}} \left[\frac{\cos \theta}{\pi(h+r)^2} \right] \underbrace{\left[\frac{P_t \tau_t \tau_r A_r}{(\text{SNR}) \left(\frac{2ek^2 \Delta f P_r}{S_c} \right)^{1/2}} \right]}_{\text{Term 3}} \right\} \quad (13)$$

Term 1 is the spectrally dependent term; term 2 represents the geometric factors such as altitude and angle of incidence; and term 3 encompasses the laser equipment parameters. The

WILLOW RUN LABORATORIES

derivation of Eq. (13) is presented in the appendix to Ref. [1]. The definition of symbols for this and the following equations are given below:

- r = depth of water
- α = absorption coefficient of water
- P_t = transmitter power
- τ_t = transmittance of transmitter optics
- τ_r = transmittance of receiver optics
- τ_a = transmittance of air
- ρ_b = reflectance of ocean bottom
- $1 - \rho_w$ = air/water transmittance
- A_r = area of receiver collector
- S_c = photomultiplier cathode sensitivity (A/W)
- θ = angle between transmitter axis and water surface normal
- h = height of aircraft or spacecraft
- SNR = signal-to-noise ratio
- e = electronic charge
- k = secondary emission factor
- Δf = electrical bandwidth
- P_r = received signal power

The depth equation (13) is simplified in that all noise sources to the photomultiplier receiver are ignored except the shot noise caused by P_r , the signal power received at the detector. Since the other sources of noise are generally from 4 to 44 orders of magnitude less than P_r , their contribution is negligible. The signal power is given by

$$P_r = \underbrace{\rho_b \tau_a^2 (1 - \rho_w)^2 e^{-2\alpha r}}_{\text{Term 1}} \underbrace{\left[\frac{\cos \theta}{\pi(h+r)^2} \right]}_{\text{Term 2}} \underbrace{P_t \tau_t \tau_r A_r}_{\text{Term 3}} \quad (14)$$

As before, term 1 is the spectrally dependent term; term 2 is geometrically dependent; and term 3 covers system parameters.

Substituting P_r into the depth equation (13), it can be seen that the required magnitude of P_r is dependent upon the signal-to-noise ratio (SNR) and photomultiplier cathode radiant sensitivity (S_c) as follows:

$$P_r = (\text{SNR})^2 \left(\frac{2ek^2 \Delta f}{S_c} \right) \quad (15)$$

Using this result, P_r can be eliminated from the range equation, leaving

WILLOW RUN LABORATORIES

$$r = \frac{1}{2\alpha} \ln \left\{ \rho_b \tau_a^2 (1 - \rho_w)^2 \left[\frac{\cos \theta}{\pi(h+r)^2} \left[\frac{P_t \tau_t \tau_r A_r}{(SNR)^2 \left(\frac{2ek^2 \Delta f}{S_c} \right)} \right] \right] \right\} \quad (16)$$

Inversion of the range equation (16) shows that the peak power required to penetrate to a given depth of water is proportional to $e^{2\alpha r}$, illustrating that the power required by the transmitter increases rapidly with small increases in α . For this reason, it is mandatory that the laser output fall in the 0.51- μ m to 0.56- μ m portion of the spectrum, where α is relatively small. From physical characteristics data (see Ref. 1, p. 52), it is seen that high-powered lasers ($P_t \geq 10^9$ W) exist for 5 wavelengths in the 0.3- μ m to 0.7- μ m spectrum, with 2 of these in the low α region. Table 2 lists these wavelengths, the corresponding attenuation coefficients for mean coastal waters, and the attenuation ($e^{2\alpha r}$) for depths of 10 m and 1 m.

TABLE 2. WAVELENGTHS AND CORRESPONDING COEFFICIENTS FOR MEAN COASTAL WATERS, AND THE ATTENUATION FOR DEPTHS OF 10 m AND 1 m

Wavelength	Attenuation Coefficient	Attenuation For 10-m Depth	Attenuation For 1-m Depth
0.3371	1.45	3.9×10^{12}	18.2
0.3472	1.24	5.9×10^{10}	11.9
0.5300	0.252	154	1.66
0.5510	0.264	196	1.70
0.6943	0.785	6.6×10^6	4.81

It is quite evident from the table that the attenuation outside the 0.51- μ m to 0.56- μ m region is excessive for most of the depths of interest. Table 3 presents other parameters of interest for the same 5 lasers.

The choice of a laser with a high peak power (P_t) at the wavelength of the minimum attenuation coefficient for coastal waters appears to afford the greatest potential for depth penetration to identify shallow water features. Table 4 gives characteristics for lasers operating in the

TABLE 3. ADDITIONAL PARAMETERS FOR SAME FIVE LASERS

Wavelength	Atmospheric Transmission		Coastal Seawater Reflectance	Ocean Floor Reflectance
	0.5 km	200 Nautical Miles		
0.3371	0.843	0.342		
0.3472	0.856	0.380		
0.5300	0.933	0.715	0.0612	0.04-0.24
0.5510	0.938	0.758	0.0545	0.03-0.36
0.6943	0.960	0.798		

WILLOW RUN LABORATORIES

TABLE 4. CHARACTERISTICS FOR LASERS OPERATING IN THE 0.3- μ m TO 0.7- μ m REGION

Wavelength (μ m)	Type	Material	Output (j)	Peak Power (W)	Pulse Width (nsec)	PRF (Hz)	Efficiency (%)
0.3371	Gas	N ₂ in air	0.1	10 ⁶	4	100	1.0
0.3472*	Solid State	Cr ³⁺ :Al ₂ O ₃	75	100 $\times$ 10 ⁶	10	100	0.01
0.5300*	Solid State	Nd ³⁺ :Glass	300	560 $\times$ 10 ⁶	10		1.0
0.5300*	Solid State	Nd ³⁺ :YAG	30	56 $\times$ 10 ⁶	10	100	1.0
0.5510 } 0.5950 }	Liquid Dye	Rodamine 6G in CH ₃ HO	150	2 $\times$ 10 ⁶	5	1500	0.036
0.6943	Solid State	Cr ³⁺ :Al ₂ O ₃	1500		10	100	0.1

*Second Harmonic. Operating temperature = 300°K for all three wavelengths. Beamwidth = 1 mrad for all except: Nd³⁺:Glass (7.5 mrad)
Cr³⁺:Al₂O₃ (2 mrad at 0.6943 μ m)

0.3- μ m to 0.7- μ m region. This listing of Q-switched lasers has standardized the outputs to 10-nsec (or less) pulses at a pulse-rate-frequency (PRF) of 100 Hz. Since the output power is a constant percentage (70% and up) of the rated average output power, higher PRF's and narrower pulse widths must be traded off at the expense of lower peak powers and higher processing bandwidth requirements.

The most powerful laser listed in Table 4 is the second harmonic of the 1.06- μ m Nd³⁺:Glass laser. A large laser, its rod is 94-cm long with a 3.8-cm outside diameter and a 3-cm core diameter. A closed-cycle liquid cooling system is required. Optical pumping is provided by four 1-m flashtubes with a required total input power of 180 W.

Electronic processing of the laser data is complicated because of the narrow pulses involved. For example, a 5-nsec pulse width requires high signal-to-noise ratios and 200-mHz bandwidths in the video amplifiers and preamplifier. The range resolution R_n in water for such a system is given by

$$R_r = \frac{CT}{n_w}$$

where C = velocity of light in vacuo (2.99793×10^8 m/sec)

T = pulse width (sec)

n_w = index of water refraction (1.33338).

WILLOW RUN LABORATORIES

Thus, the range resolution for a 5-nsec pulse-width is 1.12 m. Range resolution can be improved an order of magnitude by using a 2-gate system which tracks the received signals from the water surface and ocean floor, but it is difficult to implement with a single pulse (i.e., no integration). The fine resolution described above will be degraded somewhat because of the scattering of the beam in the water and (for the satellite case) the curvature of the earth, both of which cause stretching of the received signal pulses.

The peak power which will be used depends indirectly upon the desired data rate. If it is assumed that a data point is desired for every meter of flight line traversed, an aircraft flying at 120 knots will require a PRF of 60 Hz and a satellite orbiting at an altitude of 200 nautical miles will require a PRF of 7500 Hz. Using a pulse-width of 10 nsec, the peak power of the highest power Nd^{3+} :Glass laser will be 5×10^8 W for aircraft and 4×10^6 W for spacecraft.

The required power input to the Nd^{3+} :Glass laser is 180 W, which can be supplied in an aircraft but which might pose problems in a satellite. Since almost all (99.76%) of this input power has to be dissipated as heat with liquid coolant and heat exchangers, the satellite will be further burdened by the size and weight of the cooling system for the laser. It is probable that in a satellite laser output, peak power may have to be sacrificed in order to obtain acceptable weights for prime power and cooling systems.

4.1. OPERATIONAL CONSIDERATIONS

Data processing, whether by automatic equipment or human operators, requires that the signal be greater than the system noise. Human operators require less signal-to-noise ratio (SNR) than machine processors. Since the data rates are 60 points/sec for aircraft and 7500 points/sec for a satellite, human operators will be unable to handle the results. Thus, automatic data processing will be required and higher SNR will be necessary.

Digital communications and pulsed radar theory show that $\text{SNR} = 11.1$ is required for a probability of error equal to 0.1; further reduction of the probability of error to 0.01 (1%) requires $\text{SNR} = 20$. All calculations which follow are based on the higher SNR, yielding a detection probability of 99%.

The accuracy of the results will be affected by refraction of the laser beam by the water. If the beam strikes the water at an angle, it will be refracted toward the normal. The angle at which the beam strikes the water will in turn be affected by the presence of waves. The average slope angle of ocean waves usually varies from about 3° to 6° , although the shallow depths of coastal waters can increase this to 19° . With such high incidence angles, the laser beam will be refracted away from the normal and the measured depth will be too large, indicating deeper-than-actual water, the opposite indication from what is needed for identifying hazardous underwater features.

WILLOW RUN LABORATORIES

Much of the problem caused by surface wave effects can be eliminated by scanning. To maintain the same spatial resolution, therefore, the data rate will have to be increased. The increased data rate will result in decreased peak power of the laser transmitter because of the required increase in the PRF.

4.2. PERFORMANCE CALCULATIONS

A computerized tradeoff study of laser depth-ranging systems was presented in Ref. [1]. Following publication of the study, it was discovered that errors in the computer outputs changed the results of the study. Rather than completely redoing the tradeoff studies, it was decided that some typical parameters would be used to make the calculations in order to give an idea of what is practical at present. Table 5 lists those typical parameters for a profiling system carried by an aircraft at a 0.5-km altitude and in a satellite orbiting at a 200-nautical-mile (370-km) altitude. In both cases, a $0.5330 \mu\text{m Nd}^{3+}$:Glass laser was used, with a data patch spacing of 1 m. An RCA 7029 photomultiplier (S-17 spectral surface) is used in both receivers. On the basis of the data listed in Table 6, the values of α and of r (for mean coastal waters) were calculated and are given in Table 6.

TABLE 5. LASER DEPTH-RANGING SYSTEM PARAMETERS AND OPERATIONAL CONDITIONS

Operational Conditions	Aircraft	Satellite
Altitude (km)	0.5	370
Ground Speed (m/sec)	62	7475
Illuminated Patch Diameter (m)	0.05	1.85

Ocean Floor Reflectance (ρ_b)	0.10	0.10
Laser System Parameters		
Transmitter: Type	1-Stage Oscillator	1-Stage Oscillator
Peak Power (W)	5×10^8	8×10^6
Pulse Width (nsec)	10	10
Pulse-Repetition-Frequency (Hz)	60	7500
Power Input (W)	180	360
Aperture Diameter (cm)	20	1900
Beam (mrad)	2.1	0.005
Transmittance of Optics	0.97	0.97
Receiver: Type	Pseudo-Cassegrainian	Pseudo-Cassegrainian
Aperture Area (π^2)	1.0	1.0
Transmittance of Optics	0.450	0.450
Electronic Bandpass	100 mHz	100 mHz
SNR	20	20

WILLOW RUN LABORATORIES

As indicated by the figures in Table 6, significant depth penetration from satellite altitudes can be obtained only at the expense of reliability of detection. This would indicate that the data rate (PRF) must be reduced and/or the input power increased in order to regain reliability at satellite altitudes. The implications of such modifications have been discussed previously.

2001 Wildlife Damage Survey

7.7 Percent of Crop Value Lost to Deer and Geese

Maryland farmers lost \$17.2 million of corn, soybeans and wheat to deer or geese during 2001, translates to Maryland farmers losing 7.7 percent of the crop value to deer and geese. Soybean acres for the greatest economic loss, totaling \$9.1 million, 11 percent. Corn losses were \$6.6 million, 5.8 percent and wheat \$1.5 million, 5.6 percent. Deer damage resulted in losses of \$13.6 million, 6.1 percent, while geese losses were \$3.6 million, 1.6 percent.

Production losses totaled 6.0 million bushels. Corn losses were 3.2 million bushels, soybean losses are 2.2 million bushels and wheat accounted for 0.6 million bushels. Production losses to deer were 4.7 million bushels and geese 1.3 million bushels.

In terms of yield, losses to deer were most severe in Central and Western Maryland, while geese damage greater on the Eastern Shore. Corn yield losses of 9.6 bushels per acre and 7.4 bushels per acre were reported in Central and Western Maryland, respectively. The Lower Eastern Shore reported the highest soybean loss of 6.1 bushels per acre.

Sixty-two percent of farms reported deer or geese damage to one or more crops. Damage was reported on percent of farms raising corn, 58 percent of farms growing soybeans and 27 percent of farms with wheat.

Maryland 2001 Crop Loss from Deer

Region	Crop	Acres Harvested	Harvested Yield (bushels)	Average Yield Loss (bushels)	Production Loss (bu)	Economic Loss (\$)
Western Maryland	Corn	5,200	124,4	7.4	40,100	83
	Soybeans	300	34.7	9.9	1,301,250	2,843
	Wheat	200	45.7	2.0	440	1

USDA FORECASTS RECORD-SETTING CORN CROP FOR 2007

Washington, Aug. 10, 2007 – U.S. corn production is projected to reach a record-setting 13.1 billion bushels, 10.6 percent more than the 2006 crop.

Based on conditions as of August 1, 2007, the U.S. corn crop is projected to average 160.4 bushels per acre, up 3.7 bushels from last year's average of 156.7 bushels per acre. The average yield is based on 160.4 million acres of corn for grain, up from 156.7 million acres in 2006.

Yield forecasts are higher in the Corn Belt, particularly in the Delta. Meanwhile, hot, dry conditions in the Southeast and eastern Corn Belt, Ohio Valley and parts of the South are expected to reduce yields in those areas.

2002 Dairy Producer Opinion Survey

November 2002

Wisconsin Milk Production To Recover

Milk production is expected to increase in Wisconsin during the next five years according to a survey conducted by the Wisconsin Agricultural Statistics Service. This statewide survey of producers asked for their plans with the assumption that milk prices for the next five years will be at the same level as the past five years. The survey was conducted during May and June 2002.

Based on the survey, 60 percent of producers expect to keep the same herd size, 20 percent plan to increase herd size, and 20 percent intend to discontinue milking by 2007. Actual results will depend on future milk prices, input prices, financing availability, crop yields, and other factors.

The number of herds projected for 2007 shows that the diversity of small to large herds will continue. The most prevalent herd size will remain at 50 to 99 cows.

All Milk Price, Wisconsin Annual Average, 1985 - 2002

Wisconsin Dairy Herds by Herd Size

Milk cow herd size	May 2002 herds	May 2007 herds (projected) %	Change 2007/2002
1 - 29	2,800	1,440	-45
30 - 49	4,700	3,440	-27
50 - 99	7,400	5,600	-24
100 - 199	1,900	2,080	+9
200 - 499	700	600	-29
500+	200	440	+120
Total	17,500	19,900	+20

1/7The May 2007 projection is based on farmers' opinions May-June 2002, with the assumption that milk prices for the next five years will be at the same level as the past five years.

Small Dairy Farms Plans for May 2007

Herds	Keep same herd size	Increase herd size	Discontinue milking
Number	47	17	38
Percent	71	9	20
2,800	63	19	18
1,900	53	37	10

News Release

November 30, 2005 Ron Beck

Landsat 5 Experiencing Technical Difficulties

On November 26, 2005, the back-up solar array drive on Landsat 5 began exhibiting unusual behavior. The solar array drive maintains the proper pointing angle between the solar array and the sun. The rotation of the solar array drive became sporadic and the solar array was not able to provide the power needed to charge the batteries. Maintaining power to the batteries is critical to sustain proper operation of the spacecraft. The primary solar array drive failed under similar circumstances last January. As a result of this current situation, imaging operations will be suspended for at least the next two weeks or until attempts to solve the problem have been resolved.

State level accuracies
are very high

Producer's Accuracy: relates to the probability that a ground truth pixel will be correctly mapped and measures errors of omission.

Errors of Omission: occur when a pixel is excluded from the correct category.

User's Accuracy: indicates the probability that a pixel from the classification actually matches the ground truth data and measures errors of commission.

Errors of Commission: occur when a pixel is included in an incorrect category.

Kappa Coefficient: A statistics measure of agreement, beyond chance, between two maps.

FOREWORD

This manual has been prepared by staff cartographers and soil scientists primarily for soil scientists and others directly engaged in the national cooperative soil survey of the United States. Many of the principles may be helpful to others.

Perhaps the first use of aerial photographs for soil surveying of a whole county was in the soil survey of Jennings County, Indiana, about 1929. Since the middle 1930's soil surveying in the United States has been done on aerial photographs. This technique became available about the same time that the concept of a soil as a profile was extended to the concept of a soil as an individual, three-dimensional body on the surface of the earth.

The use of aerial photographs, first of all, makes possible increased accuracy in plotting the soil boundaries. Since the photographs show many more landscape features than ordinary planimetric maps or planetable sheets, the soil scientists have abundant control for plotting boundaries between soils identified in the field. The field soil scientist is also relieved of a large part of the job of plotting houses, roads, and other features required for users of soil maps. In fact, the features that can be seen clearly on the ground and on the photos serve as control, both for the soil scientist in the field and for the user of the soil maps.

Besides using photographs as a base on which to plot results of their field examinations, soil scientists have developed skill in interpreting photographs for clues to the kinds of soil and to the location of soil boundaries both before and during the field mapping. In low-intensity soil surveys they can make reasonable estimates of soil boundaries in areas between those examined in the field. The best reconnaissance soil surveys are made with aerial photographs. Such soil maps guide the establishment of priorities for the detailed soil surveys needed for operational planning. All these uses require high-quality photographs.

The replacement of planetable sheets by photographs as field sheets also increased the requirements of cartographic engineering skill for accurate compilation. The greater accuracy and the saving of the time of soil scientists more than compensate for the exacting job of map assembly. Published soil maps on controlled photographic mosaics help the user locate himself on the map and thus improve his accuracy of reading the kinds of soil on specific tracts of land.

Great progress has been made in soil mapping by photo interpretation accompanied by full examination of the soils at frequent intervals. While mapping soils, the soil scientist has two immediate problems: (1) With what kind of soil does this individual soil belong? (2) Where are its boundaries?

The photographs can be interpreted more accurately on the location of soil boundaries than they can on the exact classification of the soil. After close field study, however, a highly skilled soil scientist can identify kinds of soil in several kinds of landscape.

Soil scientists must always recall that soils have depth. Many aerial photographs do not show the surface of the soil itself, let alone the several horizons beneath it. Accurate soil maps cannot be made without deep examination of the soils.

Similar patterns on aerial photographs can be misleading. A combination of landform and vegetation that can give accurate clues to kinds of soil can suddenly fail elsewhere because of undetected changes in one or more aspects of climate, lithology, or land use history. What are indicator plants for one kind of soil only a few miles away can be indicator plants for a different kind of soil that is highly contrasting in terms of its use potential. But with a few examinations

of soils in depth, the relations can be clarified and aerial photographs can be used for accurate interpretation.

Variations among the lower soil horizons, or among layers just beneath the soil, may have no associated surface indication under wild vegetation or extensive use. Yet these features are highly significant under more intensive use. In deserts, for example, salt-rich layers and impermeable layers deep within the soil—which have no influence on native plants—can be of the utmost significance if the soils are irrigated. Thus soil surveys of arid land to guide irrigation require many field examinations in depth.

As the purposes of the soil survey require increasing detail and accuracy of interpretations influenced by lower horizons, relatively more dependence must be placed on field examination and less on aerial-photo interpretations. To be satisfactory, the highly detailed soil maps needed for consolidating fragmented holdings and for planning extensive irrigation works, must be developed with many field examinations. Yet in all soil surveys advanced aerial interpretation is extremely helpful for planning and for anticipating the kinds of problems to be dealt with. Experienced soil scientists use photo interpretation a great deal both for estimating soil boundaries and for identifying kinds of soil for low-intensity surveys of rangeland where the mapping units commonly are soil associations.

This manual is based mainly on experience in the national cooperative soil survey during the last 30 years. The highly technical aspects of photogrammetric engineering have been avoided, but references are cited to fuller discussions.

Several illustrations show how keys for correlating photographic images and kinds of soil can be prepared and used in the field.

Although many helped prepare this manual, special credit should be given to F. M. Orsini and C. W. Koechley, who directed its preparation, and to the following, who made major contributions and helped in its organization: M. E. Austin, J. L. Bryson, D. K. Crook, C. M. Ellerbe, R. M. Hooper, B. L. Matzek, A. C. Orvedal, J. D. Rourke, and W. E. White.

CHARLES E. KELLOGG,
Deputy Administrator for Soil Survey.

AERIAL PHOTOGRAPHY

An aerial photograph is today's most complete and informative, yet most economical, representation of the earth's surface. Aerial photographs give perspective views of the terrain. They reveal hill and dale, soil and water patterns, wonders and ravages of nature, and works of man. The Soil Conservation Service (SCS) was an early pioneer in recognizing the merits of making use of aerial surveying when, in 1934, it contracted for more than 100,000 square miles of photography.

Aerial photographs are widely used in soil surveying, farm and ranch planning, soil and forest conservation, irrigation and flood-prevention studies, timber estimates, crop-area measurement, highway planning, railroad and power-transmission location, geological research, and municipal planning. Through the science of photogrammetry, they are used as the basis for constructing precise topographic, planimetric, and controlled aerial mosaic maps.

No single combination of survey scale and lens focal length can be applied to all situations; many types and scales of aerial surveys are continually being made. In many instances aerial photographs can be used economically

only when the survey is flown at or near a given scale. Accuracy in compiling large-scale maps requires a large-scale aerial survey, whereas economical production of small-scale maps requires smaller scale survey. Also, most stereoscopic plotting instruments require surveys flown with 9- x 9-inch cameras equipped with 6-inch-focal-length lenses. Other plotting instruments require camera lenses with focal lengths of 3.5 to 12 inches, depending upon plotter design and aerial negative format. The longer 8 $\frac{1}{4}$ -inch-focal-length lenses produce photographs that are best for direct use for soil surveys and photo interpretation as used in SCS.

In addition to various scales and lenses, aerial surveys are flown with various cameras and camera angles. Single-lens or multiple-lens cameras can be used. Also, multiple cameras can be mounted with the axes of the lenses inclined to the surface of the earth to obtain converse or convergent low-oblique photography. A vertical aerial photograph, however, is the best base for soil mapping and photo interpretation, and nearly all aerial photographs for soil surveys are made with vertically mounted single-lens cameras that expose a 9- x 9-inch image area.

AERIAL SURVEYS

In the 1930's there were wide differences among surveys being flown by the various agencies of the U.S. Department of Agriculture (USDA). To provide aerial surveys that would suit most needs in agriculture, USDA agencies, in 1937, agreed to adopt a standard scale of 1:20,000 for these surveys. They were to be flown with a vertical camera equipped with an 8 $\frac{1}{4}$ -inch-focal-length lens, which would expose a 7- x 9-inch image area.

To establish conformity among aerial surveys made by these agencies, Standard Specifications for Aerial Photography for General Map Work and Land Studies were developed. Since that time, nearly all of the United States has been flown at the scale of 1:20,000 under these

"standard" specifications. Special surveys, however, are flown at 1:40,000, 1:31,680, 1:15,840, 1:10,000, 1:5,000, and other scales.

SCS modifies specifications for aerial surveys to meet requirements of a particular job and revises them to take advantage of developments in technology and improvements in materials and equipment. Specifications are revised in coordination with other USDA agencies. A summary of the latest specifications follows.

FACTORS TO BE CONSIDERED

Many geographic, physical, technical, and economic factors must be considered before a schedule of advertisement can be prepared for aerial surveys. The ultimate use or objective

of the survey must be known: Is it to be of general use, for which 1:20,000 standard flying is required; or is it to be used primarily for topographic mapping at a larger scale? Does the elevation or the type of photography require special flying equipment? Nearby surveys should be investigated to eliminate small gaps between surveys that would be expensive to fill in later. In addition, Government agencies coordinate their activities to prevent duplication. These factors help determine the survey boundary, scale of photography, and focal length of the camera lens.

TIME FOR FLYING

Contracts that enable contractors to keep their plants and personnel busy throughout the year and to take optimum advantage of favorable seasonal conditions have a direct bearing on the cost of surveys. Therefore, economical planning requires close study of such regional weather characteristics as the anticipated number of "photographic days" for each month for each survey area.¹ Such factors as geographic latitude and solar altitude must be considered to reduce or eliminate objectionable shadows in rugged areas. Generally, photography is undertaken only during that part of the day when the sun is 4 hours or more above the horizon. But in areas of little relief that have only slight differences in tone, the position of the sun may be used to emphasize landforms by introducing shadow patterns.

Most aerial surveys must be flown when the ground is free from snow. This limits the flying season in colder sections.

To show the earth's surface, photographs should be taken when trees are free of leaves and other vegetation is minimal. This limits the flying season to a few weeks in early spring and late fall. Since atmospheric conditions further limit the flying time, restricting flying to seasons when trees are free of leaves is impractical except for projects that require only a few weeks. A large project flown under such limitations would require excessive equipment to complete the job in a reasonable time. In SCS, aerial surveys made specifically for large-scale topographic mapping by stereo-plotting equipment are usually flown when deciduous

trees are bare. Most of these special projects are small.

CAMERAS AND LENSES

Precision 9- x 9-inch cameras and appropriate lenses are specified so the photography will meet minimum requirements and be widely useful. The cameras must be constructed to withstand vibration and temperature changes. Collimation or fiducial markers must be built into the plane of the film and secured to the magazine or to the inner cone of the camera so that negatives will reproduce the markers in each exposure. Fiducial marks are midway on each of the four edges of the photographs. Lines joining opposite members of the two pairs of markers will intersect at the optical center (principal point) of the exposure. Specifications also require a camera that is designed to permit testing procedures. The lens must have high resolving power to provide sharply defined images. Low distortion is required to maintain true perspective. For general use 1:20,000 surveys, the focal length is about $8\frac{1}{4}$ inches (210 ± 4 mm). For topographic mapping surveys, the focal length generally used is about 6 inches (152 ± 3 mm).

Test reports of the camera and lens must be prepared by a testing organization or Government unit approved by SCS. Reports must be submitted before the contract is awarded. These tests determine whether the camera and lens meet accuracy requirements. Test reports include the resolving power, the distortion pattern, the equivalent² and calibrated³ focal lengths of the lens, and the value of distances separating opposite fiducial markers. These fiducial measurements can be used to determine the dimensional stability of exposed negatives and of reproductions processed from them. Also, when compared to corresponding measurements on a reproduction, these distances can be used to determine the precise degree of enlargement.

² The equivalent focal length is the distance measured along the lens axis from the rear nodal point to the plane of best average definition over the entire field used in the aerial camera.

³ The calibrated focal length is an adjusted value of the equivalent focal length computed to distribute the effect of lens distortion over the entire field used in the aerial camera.

¹ A photographic day is one during which there is no more than 10 percent cloud cover.

FILM

The specifications require fine-grained, high-speed, polyester base, panchromatic film, or its equivalent. This type of film gives a good range of densities from black to white of all the colors. Panchromatic film is used for most surveys because of its all-round adaptability and low cost. Polyester base is exceptionally stable and eliminates any problem of dimensional changes caused by the film.

Since color aerial surveys for general use in SCS are not yet practical, the specifications do not list this type of film. Color aerial photography is especially limited because of processing difficulties. The cost for making color prints is now considerably more than that for making black-and-white prints. Color aerial photography has improved the accuracy of certain kinds of photo interpretations, however, especially for the military, for geologic investigations, and for forest-disease studies.

Similarly, infrared aerial photography in SCS is limited, and specifications do not mention this type of film. Infrared aerial film is sensitive to a portion of the infrared spectrum, which is not visible to the human eye. Since the film is also sensitive to a portion of the visible spectrum, true infrared photography is obtained by exposing the film through a deep red filter, which permits recording only the infrared rays. Thus, reproductions from true infrared aerial photography have a distortion of density values of the various reflected color tones. For example, green foliage of deciduous plants appears very light, as though covered by heavy frost. Differences between tones of certain species of trees and vegetation are more pronounced. Bodies of water and areas in shadow appear black. The more drastic effects of true infrared photography may be modified with a minus blue (yellow) filter, which permits recording a portion of the visible spectrum as well as the infrared portion. Modified infrared photography has many of the characteristics of true infrared photography, but it also retains some of the characteristics of panchromatic photography. In USDA, modified infrared photography is used principally by the Forest Service to distinguish between tree species.

ALTITUDE FOR FLYING AND SCALE OF NEGATIVES

The scale of an aerial survey is generally given in terms of a representative fraction or "ratio scale"; for example, 1:20,000. The ratio scale S is determined by the lens focal length f and by the altitude or flight height H above the ground as follows:

$$S = \frac{f}{H}$$

where both f and H are in the same units of measurement. Thus, general-use, 1:20,000 surveys may be flown with an 8¼-inch (0.6875-foot) lens at an altitude of 13,750 feet above ground level. Figure 1 gives the relationship between various lens focal lengths, flight altitudes, ratio scales, and scales in terms of feet-per-inch.

The schedule of advertisement for aerial surveys for SCS specifies the focal length of the lens, the altitudes for flying, and the ratio scale of negatives. The specifications require that flight altitudes do not exceed more than plus or minus 5 percent of specified values. In flat areas the scale of the negatives will vary generally within plus or minus 3 percent but will seldom vary more than plus or minus 5 percent of true scale. In mountainous areas the scale of individual exposures of a flight can range from plus 10 percent to minus 20 percent of the specified ratio scale. Such variances are primarily due to the rise and fall of ground elevation along the flight strip. Higher ground, which is closer to the camera, produces larger scale negatives. It also produces less overlap between exposures and less sidelap between flight lines. Conversely, lower ground produces smaller scale negatives, increased overlap between exposures, and increased sidelap between flights. In some areas flight altitude must be increased to maintain satisfactory sidelap over peak elevations. This action decreases the average scale of the flight and, unfortunately, produces even smaller scales through the lower agricultural areas.

FLIGHT LINES AND SIDELAP

The direction of flight lines is north and south unless special conditions make it necessary to orient the flights in another direction. Some flights are planned in an east and west direction to parallel the higher ground elevations

Figure 1.—Altitude chart for aerial surveys.

since flights that parallel the contour direction result in more uniform scale throughout the exposures. East and west flights are also used to parallel the longer dimension of a flight area and thus reduce the number of flights. Flight lines of small areas flown for topographic mapping may be oriented in any direction or combination of directions that will result in photography parallel to the general direction of the streambed.

Spacing and locations of flight lines are also specified. This spacing together with the flight altitudes and the camera and lens combination establishes approximately 30 percent sidelap between flights. Flight lines for general use 1:20,000 photography are spaced at 2-mile intervals. In sectionized areas flight lines are over alternate section lines. Flight-line locations depend upon analysis of such factors as

the location of former flight lines of the area and adjoining areas; exposure locations of new surveys that duplicate exposure locations of former surveys are generally desired. In addition, the location of particular sites of interest may dictate flight-line locations. With proper planning, these sites may fall entirely within a single photograph or within a single flight line. The minimum and maximum sidelap are specified at 15 percent and 45 percent, respectively. Some deviation from these values is permitted: for instance, within an area where there is extreme variation in elevation.

Flight lines are usually required to be continuous across the length of the area to be photographed. Breaks in flight lines are permitted when clouds, insufficient overlap or sidelap, or other conditions require re-flying a portion of a flight line.

OVERLAP

Exposures are made at intervals that result in an average overlap of about 60 percent with the preceding photograph in the flight. A minimum of 55 percent and a maximum of 65 percent overlap is specified. Overlap of 60 percent provides systematic coverage that is adequate for stereoscopic viewing of any point. Greater overlap than necessary increases the number of exposures required and therefore increases the cost. Average overlap of less than 60 percent increases the possibility of stereoscopic gaps. Such gaps cause a loss of stereoscopic views of the areas which eliminates or lessens the value of the survey for mapping. Whenever breaks in flight occur, reflights are necessary and should cover at least 100 percent overlap of end exposures at the break in flight to assure stereoscopic pairs through the "break" area.

BOUNDARY COVERAGE

Where the boundary of an area is perpendicular to the flight lines, the first and last photograph on each flight line will fall outside the project boundary. When the boundary is at an angle with flight lines, exposures at the ends of flight lines will provide stereoscopic coverage to a point at least 1 mile beyond the boundary.

Where the boundary of the area is parallel to the flight lines, the sidelap beyond the boundary will not be less than 15 percent.

CRAB

Crab of an aerial photograph is caused by failure to orient the camera with respect to the ground track of the airplane. As a result, sides of the photographs are not parallel to the line of flight. For general use photography, any two or more consecutive photographs may not be crabbed more than 10 degrees as measured from the plotted flight line. For mapping photography, any two or more consecutive photographs may not be crabbed more than 5 degrees. Within these limits, crab alone does not cause problems in the use of photographs.

TILT

Specifications limit the tilt of any negative to no more than 4 degrees. Tilt may not average more than 2 degrees in any 6-mile section or

more than 1 degree for the entire unit.⁴ Relative tilt between any two successive negatives may not exceed 6 degrees.

Image displacements due to tilt are generally negligible compared to displacements due to ground relief. Tilt of a photograph may cause image displacements that produce scaling errors of as much as 1 or 2 percent; ground relief could cause displacements that produce scaling errors 10 percent or more, depending on the ruggedness of terrain. In an area of flat terrain, displacement caused by tilt can be the principal cause of a small error in scale.

IDENTIFICATION OF EXPOSURES

Each aerial negative is marked with the date of exposure, an alphabetical symbol, the serial number and letters of the roll, and the serial number of the exposure on the roll. For example:

10-8-62

ABC-12DD-112

In addition, the abbreviation of the standard civil time of day of the exposure, the agency initials, and the approximate scale of the negatives are marked on the first and last negatives of each flight line and at each break in a flight line. For example:

10-8-62 12:15 SCS 1:20,000 ABC-12DD-112

The identification is marked within the exposure area along the northern side of the negative for north and south flights and along the western side for east and west flights.

In most exposures the alphabetical symbol alone will identify the county. In some the symbol identifies only the aerial survey project. Further investigation is required to ascertain the county within the project.

Each roll of aerial film exposed in a unified block of flying is numbered in an unbroken series beginning with number 1. A suffix of alphabetical letters is made to the roll numbers to differentiate between multiple surveys of the same county. Each exposure within a roll is also numbered in an unbroken series beginning with number 1. Exposures and rolls are thus numbered in the sequence in which they are flown. Because of weather, rejections, and

⁴ "Unit" means a county, counties, or parts thereof having the same designating symbol.

other factors, flight lines are seldom flown entirely in consecutive order. Therefore, there is no particular pattern to the roll numbers or to the direction of exposure numbers that make up the final coverage.

PHOTOINDEX

Photoindex sheets of each county or area are prepared by photographing an assembly of contact prints from the aerial negatives. Photographs in the assembly are laid so that corresponding images match reasonably well and the numbered edges are exposed to show the identity of each print. This assembly is copied on 20- x 24-inch negatives at a scale of 1: 63,360. Each sheet is identified by a title, which shows the county or area name, sheet number, alphabetical symbol, agency and contractor credit lines, graphic scale, and other data such as survey scale and year of flying. County and unit boundaries are then delineated on the index negatives.

Although the individual contact prints are not

precisely matched, a photoindex is a fair mosaic and can be used for advance planning and broad reconnaissance surveys in many fields. But an understanding of its accuracy is essential to appraise the results that may be expected if the index is used directly as a map base.

Since indexes are a compilation of contact prints, there may be considerable difference between prints of one flight line compared to prints of an adjoining one. Consequently, mismatches and scale differences may be expected in the index assembly. Deviation in the scale of aerial negatives is caused primarily by ground relief; therefore, accuracy that can be expected within an index sheet is generally proportional to the amount of ground relief. For example, in nearly flat areas, most mismatches between prints used in the index assembly should be within 0.10 inch on the final index and no mismatch should exceed 0.15 inch plus that caused by ground relief. For rugged terrain, mismatch between prints used in the assembly may amount to 0.50 inch or more.

PHOTOGRAPHIC REPRODUCTIONS

SCALE OF REPRODUCTIONS

Contact prints, since they are made at the same scale as the negatives, retain all scale deviations of the negatives. Within limitations, enlargements can be made to any desired scale if enlargement factors are computed. To compute an accurate enlargement factor, the scale of the negative must be determined. This scale is usually preferred in terms of feet-per-inch and is determined by the following relationship between horizontal ground distance GD and photograph distance pd , measured between the same two identifiable points:

$$\text{Scale in feet-per-inch} = \frac{GD}{pd}$$

where ground distance GD is in feet and photograph distance pd is in inches. The enlargement factor can now be computed simply by dividing the feet-per-inch scale of negative by the feet-per-inch scale of enlargement desired. A common, though less accurate, way to obtain a ground measurement is to scale the distance from a map. Where accurate scales are required for many reproductions covering a unified area, a slotted-templet radial-control net

may be established. Most aerial surveys flown for general use by USDA agencies have been scaled from radial-control nets. Where control nets have not been established, however, "theoretical" enlargement factors may be used. Theoretical factors are determined by dividing the ratio scale of enlargement desired by the ratio scale planned for the aerial survey. Enlargements made with a theoretical factor have the same percentage of scale deviations inherent in the original negatives. For example, if the scale of the original negative is 5 percent large, the scale of enlargement will also be 5 percent large.

Enlargements projected up to four or more diameters may be made. Film emulsion grain and other conditions cause some loss of sharpness of detail. Therefore, enlargements in excess of this magnitude are not recommended. Table 1 gives average image size of enlargements from the more common survey scales. Although a smaller scale aerial survey will result in fewer photographs for coverage of a given area, a greater enlargement is required to produce a photograph of a given scale when com-

TABLE 1.—Average image size of enlargements

[Approximate quantities of stereoscopic reproductions required to cover an area of 1,000 square miles are indicated within parentheses]

Ratio scale of survey	Scale of enlargement					
	1 inch=400 feet	1 inch=660 feet	1 inch=1,320 feet	1 inch=1,667 feet	1 inch=2,640 feet	1 inch=3,333 feet

1:15, 840	16 x 16 inches (2,060). ² 30 x 30 inches (1,030).	18 x 18 inches (1,030).	9 x 9 inches (1,030).	(1)-----	(1)-----	(1).
1:20, 000	20 x 20 inches (1,300). ² 38 x 38 inches (650).	23 x 23 inches (650).	12 x 12 inches (650).	9 x 9 inches (650).	(1)-----	(1).
1:31, 680	31 x 31 inches ³ (520). ²	19 x 19 inches (520). ² 36 x 36 inches (260).	18 x 18 inches (260).	14 x 14 inches (260).	9 x 9 inches (260).	(1).
1:40, 000	(4)-----	24 x 24 inches ³ (320). ²	23 x 23 inches (160).	18 x 18 inches (160).	12 x 12 inches (160).	9 x 9 inches (160).
1:50, 000	(4)-----	30 x 30 inches ³ (200). ²	15 x 15 inches (200). ² 29 x 29 inches (100).	23 x 23 inches (100).	14 x 14 inches (100).	11 x 11 inches (100).
1:60, 000	(4)-----	35 x 35 inches ³ (140). ²	18 x 18 inches (140). ² 34 x 34 inches (70).	15 x 15 inches (140). ² 27 x 27 inches (70).	17 x 17 inches (70).	14 x 14 inches (70).

¹ Reduction; less than 9 x 9 inches.

² Only physical coverage (nonstereoscopic) in the image size shown. Enlargements are processed in sections by the method given in figure 2.

³ Enlargements in excess of 4.3 diameters.

⁴ Not available.

pared to enlargements made from larger scale aerial surveys.

Where enlargements will produce photographs too large to be handled conveniently and economically, reproductions may be made from sections of each negative (fig. 2). Two sectional enlargements are made from each succeeding negative, namely, a "right-center area" and a "left-center area." The principal advantage of this system is that complete physical coverage is processed from only the more accurate portions of the aerial negatives. Right-center and left-center reproductions are identified merely by adding an R or an L, respectively, to the exposure number. For example, ABC-12DD-112R and ABC-12DD-112L.

The comparison of ratio scales to other equivalents is given in table 2. Equivalents for additional ratio scales may be computed as follows:

$$\text{Feet-per-inch} \dots\dots\dots = \frac{D}{12}$$

$$\text{Inches-per-1,000 feet} \dots\dots\dots = \frac{12,000}{D}$$

$$\text{Inches-per-mile} \dots\dots\dots = \frac{63,360}{D}$$

$$\text{Miles-per-inch} \dots\dots\dots = \frac{D}{63,360}$$

$$\text{Meters-per-inch} \dots\dots\dots = \frac{\text{Feet-per-inch}}{\times 0.3048006}$$

$$\text{Acres-per-square-inch} \dots\dots\dots = \frac{D^2}{43,560 \times 144}$$

$$\text{Square-inches-per-acre} \dots\dots\dots = \frac{43,560 \times 144}{D^2}$$

$$\text{Square-miles-per-square-inch} \dots\dots\dots = \frac{(\text{Feet-per-inch})^2}{(5,280)^2}$$

with *D* the denominator of the ratio scale.

TABLE 2.—Map scales and equivalents

Ratio scale	Feet per inch	Inches per 1,000 feet	Inches per mile	Miles per inch	Meters per inch	Acres per square inch	Square inches per acre	Square miles per square inch

PAPER AND PAPER FINISHES

Aerial photographs are printed on single- or double-weight paper with glossary or semimatte surface. Single-weight paper is useful where photographs are mounted, as in mosaic assembly, or where prints must be rolled. When photographs must be folded, a special single-weight folding stock generally is used. Double-weight paper can be handled repeatedly and still remain more nearly flat and, therefore, is the paper favored for general use. Glossy finishes are usually reserved for illustrations or for mounted photographs. The semimatte surface is designed to take colored or lead pencil notations and is favored for general use.

Except for special types, photographic paper presents a minor problem of distortion. The paper is fairly stable in one direction; however, atmospheric conditions can cause distortion to 0.5 percent or more across the grain of the paper. This distortion is usually shrinkage.

When dimensional stability of the reproduction is important as in slotted-templet assemblies, photographs may be printed on water-resistant paper or on white semiopaque polyester base material. Polyester base is more stable than water-resistant paper and lies perfectly flat. Because costs are about 30 percent higher for reproductions processed on water-resistant paper and about 90 percent higher for reproductions processed on polyester base materials, reproductions other than contact prints are seldom processed on stable-base material.

SELECTION OF COVERAGE

Either alternate or stereoscopic coverage may be selected for any portion of the surveyed area. Since each exposure within a flight line is made to provide at least 55 percent overlap with the preceding exposure, every part of the surveyed area is covered by at least two overlapping photographs. Thus, a set of alternately numbered photographs will cover every part of the surveyed area. Reproductions from consecutive exposures are referred to as "stereoscopic coverage," whereas reproductions from alternate

Figure 2.—Method for making sectional enlargements.

exposures are sometimes referred to as "non-stereoscopic coverage," "physical coverage," or "alternate coverage."

Stereoscopic coverage is required for three-dimensional viewing and for reproductions to be used for photogrammetric mapping. Since the center areas of photographs are more nearly like a true map, stereoscopic coverage should also be selected where there are considerable differences between ground elevations. Where the terrain is nearly flat, however, alternate coverage may be selected for general use. Alternate coverage is more economical since only half as many photographs must be processed and used.

PERSPECTIVE CHARACTER OF THE PHOTOGRAPH

As has been stated, an aerial photograph is a perspective picture and does not show all objects in their true positions. Today's precision lenses and stable-base negatives do not cause significant distortion of images in photographs for general use; but photographic papers may. Varying ground elevation within a picture is, however, a major factor of image displacement.

In flat country, image displacement is negligible. In rolling terrain, it is negligible only near the center of the photograph. Change in ground elevation within the photograph area causes continuous change in the scale of the photograph. The tops of the hills are nearer the camera than are the valleys. Because of this, the photographic scale of hills is larger than the scale of valleys. Except in rugged areas, scale variances may not be serious; but to make effective use of photography of rugged areas, the perspective characteristics of the image must be fully understood.

Figure 3 represents image displacement

Figure 3.—Displacement due to elevation of the ground.

caused by elevation of the ground. The datum plane shown in the diagram is the level of ground elevation that produces the planned aerial-negative scale. Points A, P, X, B and C , are ground positions. The distortion- and displacement-free (orthogonal) locations of these points are shown at $A', P', X, B',$ and C' . The aerial photograph, however, shows these ground positions at locations a, p, x, b and c , which are displaced in a radial direction from the nadir point.⁵ In a true vertical photograph, the nadir point coincides with the principal point,⁶ or picture center, which is indicated as point p .

The radial displacement of any image point may be computed from the following formula:

$$d = \frac{nh}{H}$$

where d = the amount of displacement measured on the photograph

n = the distance measured from the photograph nadir to the image point

h = the difference in elevation between the ground point and the datum plane (positive if ground point is above datum, negative if below)

H = the height (flight altitude, fig. 1) of the camera above the datum plane

and where d and n are in the same units of measurement, as in inches, and h and H are in the same units, as in feet.

From the formula, ground elevations above the datum plane, such as at A , are displaced outward (positive) from the nadir; but ground elevations below the datum plane, such as at B , are displaced inward (negative). Ground elevations that coincide with the datum plane, such as at X , and ground points directly below the camera, such as at P , are not displaced. The formula also discloses that displacement varies jointly as distance n and difference in elevation h , and inversely as height H .

The net displacement caused by a difference in elevation measured from the ground to the

⁵ The nadir point, or plumb point, is the point on the ground vertically beneath the camera lens.

⁶ The principal point is the optical center of the photograph.

top of an object, such as a silo or tree, also may be computed with the above formula if H is defined as the height of the camera above the base of the object and h is defined as the height of the object.

Because the flight altitude H is equal to the lens focal length divided by the ratio scale of the survey (fig. 1), a longer focal length re-

quires a higher flight altitude to maintain a specified ratio scale. From the displacement formula, a higher flight altitude reduces displacement caused by ground elevation. The $8\frac{1}{4}$ -inch focal-length lens used for 1:20,000 photography for USDA is a compromise based on such factors as the amount of image displacement and estimated cost of surveys.

STEREOSCOPY

Stereoscopy is the science of producing three-dimensional effects from two-dimensional pictures of subjects having three dimensions and the methods by which these effects are produced. In normal vision, each eye focuses on an object from a different position and transmits a slightly different image to the brain. In the mind's eye, the two transmitted images are combined into a single three-dimensional counterpart of the original object. If one eye is closed and the object is viewed with only the open eye, however, no more than a two-dimensional image is achieved. For all practical purposes, depth or distance factors are lost and actual distances can only be judged by the comparative size of the viewed object or by the relative positions of familiar objects.

This stereoscopic principle is used to produce a three-dimensional image of the earth's surface with pairs of vertical aerial photographs. The opportunity to study vegetation, culture, drainage, and other features of the land in three dimensions gives greater value to aerial photography.

Almost anyone with good sight in both eyes, or whose eyesight can be corrected, can acquire the ability to view pairs of aerial photographs stereoscopically. Skill in stereoscopic study is gained only through practice. Initial attempts may be frustrating, but as facility in the procedures increases the stereoscopic examination of aerial photographs becomes routine.

PARALLAX

Parallax is defined as any apparent displacement of an object due to a change in position from which the object is observed. The eyes view an object from two slightly different positions because they are separated. This separation is called the interpupillary distance and is about $2\frac{1}{4}$ inches for most people but ranges

from 1.97 inches to 2.85 inches for different persons. Parts of a three-dimensional object seen by one eye are not seen by the other. Furthermore, the image of near objects seen by each eye alternately appears displaced or removed laterally in relation to background objects. This lateral displacement is "parallax." Parallax is an important factor in determining the relative distances of objects in a scene. When the eyes scan a solid object the different planes of the object are separated through parallactic displacement and the impression of relief is obtained.

BINOCULAR VISION

Most people can distinguish between well-defined vertical lines if the distance between the lines subtends a convergence angle of at least 1 minute of arc (fig. 4). A highly trained observer, however, may distinguish between lines that subtend an angle as small as 15 to 20 seconds of arc.

A person with an interpupillary distance of 1.97 inches may perceive depth in an object up to a distance of about 570 feet; a person with an interpupillary distance of 2.85 inches may see depth in objects up to a distance of about 800 feet. The highly trained observer could perceive depth to about 1,700 feet if he had an interpupillary distance of 1.97 inches, or to a little over 2,400 feet if he had an interpupillary

Figure 4.—Interpupillary distance and depth perception.

distance of 2.85 inches. Beyond this even the trained observer is unable to perceive depth or see relief. For this reason mountainous or rough terrain looks nearly flat when flying at a considerable altitude.

The following relationship between interpupillary distance PD and angle of convergence θ may be used to approximate large distances R to viewed objects:

$$R = \frac{PD}{\theta}$$

where R and PD are in the same unit of measurement, as in feet, and θ is expressed in radians.⁷

SEEING STEREOSCOPICALLY

Anyone with normal eyesight in both eyes or with corrected vision can see three dimensions, or see stereoscopically. This ability may be tested by looking at a small object at eye level about 20 feet away. Extend the forefinger of each hand and raise each to eye level. Without changing the focus of the eyes on the distant object, bring the fingertips together slowly on the line of sight. If you see an "ocular weinerwurst" between the fingertips (fig. 5), you can learn to use a stereoscope successfully.

Many persons are able to experience three-dimensional impressions while viewing pairs of aerial photographs without benefit of lenses, prisms, or mirrors, but simply with the eyes alone. This ability is acquired only by special effort and continued practice. While this ability is sometimes helpful, use of a stereoscope is more satisfactory.

Ordinarily, the eyes converge on the subject being viewed. To view a stereoscopic pair of photographs, however, the lines of sight must be about parallel so that the right eye views

the right-hand photograph and the left eye the left-hand one. At times a three-dimensional image is inverted. This inverted or pseudoscopic effect is caused by viewing the right-hand photograph with the left eye and the left-hand photograph with the right eye. The condition may be corrected by reversing the photographs to their proper positions or, if the effect is caused by looking cross-eyed, by making sure that the lines of sight do not cross.

KINDS OF STEREOSCOPES

There are several kinds of stereoscopes made by a number of optical and photogrammetric equipment manufacturers. The principal difference between stereoscopes is the optical method used to prevent lines of sight from converging at the focal plane or point of focus. The basic types are: *prism* stereoscope, *lensatic* stereoscope, reflecting or *mirror* stereoscope, or a combination of these. Some mirror stereoscopes are equipped with binoculars which magnify the image. This attachment is considered unsatisfactory for general use because the field of vision is reduced drastically. Binocular attachments, however, help to identify land survey stations and other minute detail.

The old-fashioned parlor stereoscope (fig. 6) is probably the best known prism stereoscope. It has thin wedge-shaped prisms that spread the lines of sight, slight magnification with a limited field of vision, and a critical focal distance.

A simple folding, pocket-sized, lens stereoscope (fig. 7) extends the focal length of the eyes and helps overcome normal convergence. Figure 8 illustrates the difference in the lines of sight between the spherical lens and the pris-

Figure 5.—Ocular weinerwurst.

Figure 6.—Prism stereoscope.

⁷ 20 seconds of arc is 0.0000965 radians.

Figure 7.—Lens stereoscope.

Figure 8.—Line of sight through lens stereoscopes: Left, through simple spherical lenses the distance between image points (A and A') is usually less than pupillary distance (PD)—maximum separation does not exceed $bb' = PD$. Right, prismatic lenses permit the distance between image points (A and A') to be greater than pupillary distance (PD)—prismatic deviation causes A and A' to be seen in the directions a and a' .

matic lens stereoscope. The photographs are placed at a distance from the lens equal to the focal length of the lens. Since this is much like

Figure 9.—Mirror stereoscope.

Figure 10.—Lines of sight through a mirror stereoscope.

placing the photographs at or near optical infinity of the eye, the lines of sight are nearly parallel. Most lens stereoscopes are inexpensive. They can be used effectively with 9- by 9-inch contact prints and 4-inches-equal-1-mile enlargements from 1:20,000 aerial surveys. They magnify the image about $1\frac{1}{2}$ to 2 times and are convenient for general use.

The mirror stereoscope (figs. 9 and 10) has prisms or mirrors, or both, to spread the lines of sight. The lens-mirror assembly usually can be raised or lowered until the photographic image is focused sharply. The lines of sight at the point of focus are usually about 9 inches apart. Because of this a much larger photographic area may be examined without moving the photograph or the stereoscope. Reflecting or mirror stereoscopes may be used to view 9- by 9-inch contact prints and enlargements.

OTHER WAYS TO PRODUCE A STEREOSCOPIC EFFECT

In addition to stereoscopes and pairs of overlapping photographs, anaglyphs or vectographs give a three-dimensional impression.

An anaglyph is a composite of superimposed stereoscopic images in complementary colors. This kind of composite is used to obtain the three-dimensional view in most stereo photogrammetric plotters such as the Multiplex and

the Kelsh. The overlapping portion of one aerial exposure of a stereoscopic pair is projected or printed in a color such as blue. The overlapping portion of the adjacent aerial exposure is projected or printed in a complementary color such as red which is superimposed over the blue image. Usually the image of one color is slightly offset from the image of the other color. The composite image is then viewed through a pair of spectacles which has one red lens and one blue lens. One eye sees only the blue image because the red lens neutralizes the red image; the other eye sees only the red image because the blue lens neutralizes the blue image. Thus, a three-dimensional view is achieved.

A vectograph uses polarized light rays to achieve image separation. Polarized light, the basis for the process, vibrates in only one direction within a plane, whereas ordinary light vibrates in all crosswise directions. A composite of superimposed images is prepared by transferring dyed images of the aerial exposures to a sheet of polaroid vectograph film. One side of the vectograph film polarizes light in one direction; the other polarizes light in the opposite direction. The overlapping image of one aerial exposure is dye-transferred to one side of the vectograph film; a reversed, overlapping image of the adjacent aerial exposure is dye-transferred to the other side of the vectograph film. The composite image is viewed through a pair of polarized spectacles, which has the axis of one lens at right angles to the axis of the other; one eye sees the image of only one of the pictures of the overprinted pair; the other eye sees only the other. The mental fusion of the two images forms a three-dimensional view.

STEREOSCOPIC VIEW FROM AERIAL PHOTOGRAPHS

For general use 1:20,000 surveys, exposures within the line of flight are made about 1 mile apart. In effect, the eye base is enlarged to 1 mile from the normal between-the-pupils distance of $2\frac{1}{4}$ inches. This makes possible a three-dimensional view even though the photographs were taken from a height of more than $2\frac{1}{2}$ miles. When viewing a stereoscopic pair each eye assumes a position of the camera station at the instant of exposure and the impression of slope is greatly exaggerated (fig. 11).

Figure 11.—Camera station and eye position.

This exaggeration increases as the distance between the two camera stations increases. It can be of considerable benefit when interpreting ground slope from photographs.

SELF-TRAINING

The lenses of a stereoscope must be accurately spaced and adjusted for each individual's eyes if he is to see a stereo model properly. If the lenses are spaced too far apart, the model appears concave or saucer shaped. If they are spaced too close, they give a convex or mound appearance. Either improper spacing can lead to mistakes in delineation of drainage or in other interpretations.

To adjust the stereoscope lenses, place two identical prints under the lenses of a stereoscope so that the same area can be viewed on both photographs, like a regular stereoscopic pair. Both photographs must be flat. The concave or convex effect can be noted readily by moving the lenses to the extremes, wide apart or close together, and adjusting the duplicate photographs accordingly. When the lenses and photographs are moved back and forth until an area of about 4 square inches directly under the stereoscope appears to be perfectly flat, the lenses are properly spaced for viewing stereoscopically. Mark the stereoscope so that the lenses can be set to this spacing without testing each time the instrument is used. A stereoscope with adjustable lenses that can be spaced to each individual's eyes should be used for

photo interpretation rather than one with fixed lenses.

To see stereoscopically, some control of the eyes not exercised in ordinary vision is essential. One of the simpler ways to develop this control requires but two sheets of paper with a horizontal line drawn on one and a vertical line on the other. Place one sheet below the left-hand lens of a stereoscope and the other below the right-hand lens. Focus each eye on the line appearing directly below. Hold the left-hand sheet in place and move the right-hand sheet slowly to the left or right (fig. 12). When the horizontal and vertical lines appear in the form of a cross rather than as two separate lines, the view is stereoscopic. Blinking first one eye and then the other while bringing the two images into focus may help.

A piece of cardboard placed perpendicularly between the stereoscope lenses may help keep the lines of sight parallel and help train each eye to focus separately on its subject. This exercise may tire eye muscles but will not harm them.

To practice, after the cross appears move the left-hand sheet until the vertical and horizontal lines again separate. Then, shift the sheets until the lines join once more in a cross. Repeat until "fusing" is done rapidly. Note the location of each sheet with reference to the stereoscope lenses when the lines are fused into a cross.

The centers of the lines should be 2 to 3 inches apart under the pocket stereoscope and about 9 inches apart under the usual mirror stereoscope.

Figure 12.—Location of sheets under stereoscope.

Removing and replacing the sheets trains the eyes to focus on the lines. When the lines can be rapidly fused into a cross, stereoscopic viewing of aerial photographs may be started.

Mounted pairs of stereoscopic pictures are helpful to practice viewing aerial photographs. They can be made by cutting 2-inch-wide strips covering the same ground area from adjoining aerial photographs. The strips are cut perpendicular to the line of flight. They are mounted on stiff paper so that images of identical ground points are opposite one another and about 2 inches apart. (See figures 20, 21, and 22.) Of course, the strip from the left photograph must be mounted on the left side. Mounted pairs that show particularly interesting terrain are especially helpful.

Stereoscopic pairs showing land with moderate relief and a distinct pattern of surface features should be selected for practice. The photographs should have equal tone and identical ratio scale. The optical center of each photograph is marked with a small cross (P_1 and P_2 , fig. 13). Next, the optical center of each photograph is transferred to the other (P_1' and P_2'), and a straight line is drawn between the two crosses of each photograph. This line very closely represents the flight path of the aircraft. Because of crab, the lines may not be perpendicular to the photograph edges they intersect. The pair of photographs is now placed under the stereoscope so that the center-to-center line on one photograph is a continuation of the line on the other, and the photographs are overlapped so that the center of one photograph as at P_1 and its transferred location on the other photograph as at P_1' are separated by about 2 inches. Also, these lines must be parallel with an imaginary line drawn through the centers of the stereoscope lenses.

Figure 13.—Orientation of photographs for viewing.

The photographs should be moved toward or away from one another until the crosses and connecting lines are fused under the stereoscope. As soon as this occurs one of the photographs should be shifted until fusion is lost and then moved again until fusion is recovered. This should be practiced until many of the more prominent features can also be fused rapidly. One of the more difficult and most important steps is placing the two photographs in the proper position relative to one another and to the stereoscope. Even a slight twist from parallel creates additional distortion and causes eyestrain. Viewing at an oblique angle also increases the distortion. As skill develops, however, images are fused by observing the physical features rather than by matching the crosses and lines, and photographs without such lines can be used.

OTHER PROCEDURES AND DEVICES

Many details and devices will be discovered and developed as proficiency in stereoscopic work is increased. For example, each photograph should be equally illuminated without glare, and the light should be behind the stereoscope. Photographs should be oriented so that shadows extend toward the viewer and away from the light. Shadows extending away from the viewer may invert the stereoscopic image.

The inside edge of the top photograph is frequently lifted or rolled upward to view stereoscopically part of the bottom photograph otherwise obscured by the top photograph. Figure 14 shows a convenient holder for stereoscopic pairs which systematically bends upward the overlapping portion of the top photograph. When prints are too large to bend all the excessive overlap upward, a slot may be made in a table top or supporting base, through which the excess parts may be inserted and bent downward. Or this slot may be an inch gap between two tables. Except to provide the stereoscopic view, photographs should be kept flat.

Several devices for supporting the stereoscope over the photographs have been proposed. One device mounts a vertical rod at the rear of a table and has a horizontal arm to support and swing the stereoscope over the work surface (fig. 15, top). Another attaches the stereoscope to the flexible standard of a gooseneck lamp. A third uses an accordion telephone ex-

tension unit that has a terminal support with casters at the stereoscope end. Still another method attaches the stereoscope to a storm sash friction adjuster (fig. 15, bottom); the friction disks at the three hinge points eliminate wobble but allow horizontal movement of the stereoscope over the photographs.

A very handy method of supporting a stereoscope is shown in figure 16. Simple stereoscope lenses are mounted on a drafting lamp. The stereoscope may be moved over the photographs and the light is always in proper position for excellent illumination.

A desk stand for mounting a simple pocket stereoscope may be constructed as shown in figure 17. The legs of this support occupy positions beyond the stereoscopic working area.

For field use, a shelf has been designed for attachment inside the right-hand door of a pick-up truck. The surveyor raises the shelf and puts photographs in position for stereoscopic study (fig. 18). Excess parts of the photographs are bent downward through a 1-inch slot. With this shelf a stereoscope may be used conveniently; the shelf is easily raised or lowered, and the car door can be opened or closed at any time; aerial photographs can be carried in place while the shelf is either up or down; the entire unit can be installed or removed without marring any part of the vehicle.

Figure 19 gives details for making an easy-to-use stereogram for field use.

Figure 14.—Holder for stereoscopic pairs.

A technical diagram of a mechanical linkage system. It features a vertical wooden post on the left. A horizontal arm is attached to the post via a pivot. The arm is connected to a lever mechanism on the right, which has two circular openings. This lever is positioned above a large rectangular plate that is divided into two sections by a diagonal line. The entire assembly is mounted on a base plate.

17

Figure 19.—Steps in preparing aerial photographs for easy stereoscopic viewing in the field: Mark match lines on mapping photograph (left center). On alternate adjacent photographs sketch exactly half of the mapping area (left top and bottom). With a sharp instrument, trim upper and lower lines on alternate photographs. Cut through the emulsion only across the center of each trimmed section (dashed lines, left top and bottom) and fold along the cut line with the emulsion side out. Position the trimmed sections for stereoscopic viewing (right center) and tape them outside the viewing area (right bottom). Fold under for viewing the edge of the mapping photograph (right bottom) and out for viewing the center.

SOIL INTERPRETATION FROM AERIAL PHOTOGRAPHS

Aerial photographs are widely used as a base on which to plot data about soils and to draw boundaries between kinds of soil with or without the aid of a stereoscope. Stereoscopic interpretation of aerial photographs gives a soil scientist additional clues about the kinds of soil he is likely to find and especially about where the soil boundaries lie. There are of course limitations. No one can "see" a soil on an aerial photograph. A soil is a three-dimensional unit of the landscape. It has depth. From the picture the soil scientist can see only the surface—and that imperfectly. He can see the third dimension only by digging a pit.

Yet the study of aerial photographs gives important clues about the shape of surfaces, the vegetation, and the soil color. Often these patterns are repeated over large areas. By studying examples of landscapes that make up patterns along with excavations and borings, and supplementing these with laboratory data, the soil scientist can learn the local relationships between specific kinds of soil and patterns in the photographs. This helps him in plotting soil boundaries more accurately and rapidly. It helps him with exploratory or reconnaissance soil surveys that are often made before detailed soil surveys of specific parts of a large area or region. Even so, limitations in such observations can only suggest soil identification in detailed surveys. Many soil surveys are used as a basis for predicting the systems of soil and crop, range, or forest management that can be carried economically on a sustained basis. This involves specific predictions about adapted crops and the yields that may be expected of these crops by kinds of soil under alternative systems of management. To be reliable, the kinds of soil and the soil mapping units must be identified from ground observations. The principle here is not one of "either-or." Even though we cannot make a reliable soil map from examining aerial photographs alone, the photographs should not be ignored; soil maps can be made more accurately and more rapidly with good photo interpretation than without it.

Exploratory or reconnaissance soil surveys have an important place in areas having little soil suitable for cropping or in areas where the proportion of soils suitable for cropping is unknown. If sizable areas of soils suitable for

intensive use are discovered by these surveys, they can be covered by detailed soil surveys for planning such use. Approximate identification of the kinds of soil can be made by interpretation of aerial photographs, and a suitable soil map can be produced provided that adequate examples of each kind of soil have been studied on the ground.

It is extremely important that the limitations of photo interpretation in soil mapping be understood. Some so-called "soil maps" have been made with little or no groundwork by soil scientists. Since soil maps made in this way are bound to be misleading if used for giving the definite recommendations that land users require, such work discredits both soil science and photo interpretation of aerial photographs.

There are several reasons why one cannot expect to produce accurate soil maps from aerial photographs alone. For example, certain kinds of trees and other native plants in one combination of climate and landform indicate a soil suitable for agriculture; in another combination of climate and landform the same or similar plants are not reliable guides. Man has played an important role in altering the relationships of vegetation, climate, and landform. He has removed or drastically altered the original vegetation in many places. Even though wild plants have been allowed to return, they may not be the same kind of plants as were there earlier. The soils in the northern Lake States illustrate how misleading vegetation can be. If the soils have been cut over and not burned, one type of forest comes back. If they have been cut over and burned, another type appears. If the burning continues for many years, still another type will occupy the soil for some time. Other areas of these soils may have been cultivated a while and then abandoned to wild plants of still a different association. Some places take 200 to 300 years for anything like the original vegetation to return. Unless these matters are made clear through ground study and unless the interpreter is familiar with this detailed knowledge the chances for error are great.

Most soil maps are made for giving information to land users about how the soils respond to management that involves substantial changes in the soil. On the whole, crop plants require a considerably higher nutrient status of soil

than do wild plants. Many soils that appear to be infertile in a wild landscape can be made productive through the use of chemicals, water-control practices, and proper plant species. Other soils that look the same to a casual observer cannot yet be made productive perhaps because of certain characteristics beneath the surface or perhaps because science has not yet found out how.

All soil scientists and students of plant geography are familiar with the close relationship in many places between kinds of soil and nature of the parent material, relief, climate, vegeta-

tion, and age of the landform. Thus broad soil zones do correspond roughly to broad climatic and vegetation zones. Yet near the margins between these zones some small factor such as wind velocity or amount of calcium carbonate in the parent rock may throw the soil along one course of development or another. In large parts of western Alaska for example wind velocity has probably kept the trees much farther east than they would otherwise have been. And in the Mediterranean region, differences in hardness of the calcareous rock cause sharp contrasts in soils lying side-by-side.

IDENTIFICATION ON AERIAL PHOTOGRAPHS

Before aerial photographs can be interpreted, the ground features on the photographs must be identified. Identification is by direct recognition or deduction or a combination of the two.

Objects that make well-defined or familiar images can be identified by their shape, size, and tone on single photographs or on stereoscopic pairs. Road networks, farm buildings, fields, vegetation, and bodies of water can be identified on a single photograph by shape and variation in tone. Position of objects in relation to other features helps identify the objects. Information about land use and management practices also can be learned from single photographs. Additional features are likely to be identified if stereoscopic pairs are viewed through a stereoscope.

VARIATION IN TONE

The tone of an image on a photograph depends on the amount of light reflected by the object that forms the image. Objects that reflect most of the light striking them appear light on a photograph; those that reflect a small amount of light appear dark. On photographs the tones are mainly shades of gray, but they may cover the complete range from black to white.

The amount of light reflected from an object depends on the nature and color of the surface of the object, the degree to which the object is exposed to the sun, and the angle of reflection from the object to the camera. The smooth surfaces of roads and of dry, bare soil photograph almost white from a wide range of camera positions because they reflect much light in many directions (fig. 20). Bare, moist soils photograph

darker than do bare, dry soils. Mirror-smooth bodies of water reflect a high proportion of light in a single direction and photograph white if the light is reflected directly into the camera (fig. 21). They may appear very dark or black on aerial photographs (fig. 22) if the camera lens is moved out of the line of reflected light. Most objects in the landscape, however, reflect at least a small amount of light.

EVIDENCE OF SLOPE

A surface reflects the greatest amount of light when its slope reflects the sun's rays directly into the camera and photographs lightest at this time. Thus, in any single photograph, if differences in slope of the landscape are sufficient, these differences cause variations in tone on the photograph. From the difference in tone, slope can be inferred. Frequently differences in slope not disclosed by inspection of a single photograph can be discerned by comparing two photographs of the same area taken at different times. The change in position of the sun changes the angle of reflection and shows evidence of slope.

Evidence of slope derived by comparison of tone is particularly useful in forested areas where minor variations are obscured by trees and do not show in stereoscopic observation. Trees appear lighter in areas sloping toward the sun than in areas sloping away from the sun.

SHADOWS

Shadows covering relatively large areas suggest that the landscape has steep slopes and high landforms (figs. 23 and 24). The length of shadows varies with season of year as well

as with time of day. The forms of shadows can be used to identify some structures and certain other cultural and natural features. For example, the image of a bridge may not show whether the bridge is supported by a trestle or an arch, but the shadow cast by the bridge may.

CONTRAST

Contrast refers to distinctness of tones as opposed to gradations in tones. Black and white are the extremes of contrast. Photographs with very dark and very light tones and only a few middle tones have high contrast.

The amount of contrast is determined partly by variations in the capacity of objects to reflect light and partly by the clearness of the atmosphere and by the photographic techniques used. Atmospheric haze scatters light and reduces contrast. The contrast in photographs taken on bright days is greater than in photographs taken on dull days. Soil when wet absorbs light and photographs darker than when it is dry. Contrast changes from season to season but not uniformly from region to region.

A land surface broken by variations in kinds of slope, by differences in soil, vegetation, and land use, and by manmade objects will have more contrast than a land surface fairly uniform in topography, soil, and land use. A hilly landscape in the Southeast that is marked by forests, fields in crops, freshly plowed land, and severely eroded patches produces a photograph with more contrast than a smooth area of rangeland or desert in the Southwest.

Contrast can be increased or decreased by varying the exposure time or the time for developing film and by the paper used for making prints.

SHARPNESS OF BOUNDARIES

The sharpness of boundaries between tones is affected somewhat by the photographic techniques used, but the distinctness of boundaries will differ for different objects. Boundaries of forests, wet areas, and topographic features are generally diffused; boundaries of fields, bodies of water, highways, and railroads are usually sharp.

TONE PATTERNS

Certain landforms and culture have characteristic tone patterns on aerial photographs.

Forests, fields, crops, and orchards frequently show distinguishing patterns as do networks of streams, roads, or ditches. The photo interpreter learns the characteristic patterns of the area—for example, dendritic or parallel patterns of drainageways—and uses these to help him identify objects. Figures 25–34, 39, 45, 46, and 56 illustrate various tone patterns.

PERCEPTION OF DEPTH

Some topography difficult to deduce on a single photograph may be seen readily by viewing stereoscopic pairs (figs. 32, 33, 34, and 35). Many items not identified readily on a single photograph are easily recognized; items distinct on a single photograph can be observed in greater detail. Everything that reveals itself by shape and even slight differences in tone generally can be identified with greater certainty.

With depth perception to aid him, the soil scientist needs only a little practice to distinguish rough mountains and steep, hilly, rolling, or level areas. He can improve his ability to recognize certain landscapes by frequently comparing the topography as it appears on stereoscopic pairs with its appearance on the ground.

IDENTIFICATION OF LANDFORMS AND OTHER NATURAL FEATURES

Natural features are generally more difficult to detect than are manmade objects or cultivated fields and other areas where man has disturbed the native cover. Low natural hills, for example, generally are more difficult to detect than are embankments because embankments have steeper slopes and more regular lines.

Some simple landforms such as terraces, flood plains, and sand dunes (fig. 36) can be identified by their shape, relative height, slope, and drainage pattern. Identification of features such as ground moraines, shale plains, and limestone uplands is difficult and can be inferred only in part by studying aerial photographs.

Ground Moraines.—Ground moraines in many places produce contrasty photographs because they have many small, shallow, irregularly shaped depressions and intervening gentle slopes. The slight difference in elevation between depressions and intervening slopes can be discerned on a stereoscopic pair. Soils in the depressions photograph dark; others photograph light. (See figure 45.) If there is a

Figure 27.—In this area of uniform lithology in Ohio, distinctions between soils are closely related to topographic variations readily recognized under a stereoscope. Soils on flood plains, on drainage divides, and on steep valley sides can be easily delineated. White streaks with feathered edges and orientation with slope are likely to indicate eroded areas. White streaks oriented laterally on steep valley sides may indicate rock ledges.

SCALE 1:20,000

ASCS—CWM-3K-183: CWM-3K-182

Figure 28.—The mottled pattern of light and very dark tones on a gray background represents an association of calcium-carbonate Solonchak soils, Humic Gley soils, and Chernozem soils on the till plain in North Dakota. The Solonchak soils photograph light. Those somewhat poorly or poorly drained have a finely mottled appearance and are within or adjacent to kettles. Humic Gley soils, which usually register dark, occupy the deepest parts of the kettles. Kettles are small subrounded spots with sharp boundaries. The moderately well drained Solonchak soils have a patchy appearance and are in with Chernozem soils, the gray background in the photograph; the lightest shades indicate tops of low knolls or undulations. Compare the sharp outlines of the roads, fields, and images of buildings with the diffuse soil boundaries.

SCALE 1:20,000

ASCS—1Z-5G-181; 1Z-5G-182

Figure 29.—This pair of photographs of an area in Georgia illustrates differences in topography, land use, and drainage pattern between soils in limestone valleys and on adjacent ridges of metamorphic rocks. At B are Lithosols in residuum from schist. They are strongly sloping to steep and are forest covered; the drainage pattern is dendritic. Light areas marked L are mainly Red-Yellow Podzolic soils and Alluvial soils. The Red-Yellow Podzolic soils, mainly on uplands, are in limestone residuum and are gently sloping to hilly. The Alluvial soils, on bottom lands along streams, are nearly level; the drainage pattern, modified by local sinkholes, is indefinite except along large streams.

SCALE 1:20,000

ASCS—CAW-2N-125; CAW-2N-124

Figure 30.—The gray tone in most of these photographs represents moderately dark-colored Chestnut soils in thick deposits of loess in western Nebraska. The intensely mottled light-colored pattern in the lower part represents Lithosols, exposed residual parent materials, and rock ledges on the walls of narrow, steep-sided valleys. Narrow stream bottoms form a dark skeletal network. A gorgelike cross section is easily distinguished under a stereoscope as are hard rock ledges on the valley sides.

SCALE 1:20,000

Figure 35.—The mottles on these Louisiana photographs identify mounds 30 to 75 feet in diameter and 1 to 5 feet high. Most of the soils are medium textured; those in the mounds are sandier than those between mounds. The vertical shape of the mounds show under a stereoscope.

SCALE 1:20,000

ASCS—CIK-4F-140, CIK-4F-141

Figure 36.—This pair of aerial photographs taken in eastern New Mexico provides a striking example of how dune topography is revealed with stereoscopic viewing. The soils are sandy Regosols.

drainage pattern, it is weakly expressed and generally coarsely dendritic. Ground moraines that have few depressions and soils that photograph mostly in gray shades do not produce contrasty photographs. Instead of having many irregular depressions they have a dendritic drainage that is not strongly expressed.

Shale Plains.—Shale plains appear more rugged and dissected in a photograph than do ground moraines. Where shale is level bedded the drainage pattern is dendritic. Valleys are steep sided, and all except those of many major streams are V-shaped. Slopes of valleys, hills, and divides are influenced by climate and relative hardness of the shale. In arid areas, where rainfall quickly runs off and vegetation is sparse, soft or clayey shale carves into badlands that have angular valley walls. In humid areas, the hills in shale have rounded tops and the divides are narrow and winding. Hills are lower and more rounded in soft shale than in hard shale.

Limestone Uplands.—Limestone uplands produce a different picture than do shale plains. The differences are most apparent on stereoscopic pairs. Most landforms underlain by limestone with little siliceous material have many sinkholes. Hills are more rounded than in shale plains, streams are fewer and more widely spaced, and stream valleys are more U-shaped. In siliceous limestone there are fewer sinkholes and more tributaries to main streams, and valleys—except those of major streams—tend to be narrower and more steep sided than those in pure limestone.

Rock Outcrops.—Rock outcrops, except those of very dark color, appear as light spots. A shadow is often a clue to an escarpment; on a stereoscopic pair escarpments show as abrupt changes in elevation. Stone fences are clues to stoniness, but on aerial photographs they are difficult to distinguish from other fence rows or field boundaries.

Alluvial Fans.—Alluvial fans may photograph lighter than do adjoining flood plains. But the fans will appear darker if they contain more moisture than adjacent areas. If the outer rim of the fan is wet by seepage, it will appear darker than the inner part.

Alkali and Saline Patches.—Alkali and saline patches in arid regions appear as light spots when dry and as dark spots with white rims when wet. Where there is no white encrusta-

tion or other direct evidence of alkali or salts, the salinity of the area may be inferred from the absence of vegetation or from change in appearance of vegetation. Greasewood, for example, is a large shrub that grows in saline areas where other native plants may not survive.

Drainage Patterns.—In a single photograph, main streams ordinarily can be identified easily, but the irregular curved line of tributary drains are more difficult to recognize. Success in identifying the drainage pattern depends on the relief of the area, the number of tributaries, how easily they can be seen on the photograph, and their orientation to the main stream. Tributaries can be recognized by depth and shape of valleys and slope of valley sides. Figure 37 illustrates drainage patterns.

Under the stereoscope, stream courses in heavily forested areas can be located from the topography of the valley (fig. 38). Where the gradient is steep the direction of flow can be determined stereoscopically by noting vertical differences along the stream. If a single photograph is used, direction of flow has to be deduced from studying other evidence. The width, depth, and shape of a stream channel are best observed by stereo (fig. 39). Drainage patterns are more easily detected stereoscopically even in areas of weak dissection or otherwise subdued relief. Where there are no shadows in such areas, only the larger streams can be recognized in single photographs.

Eroded Soils.—A knowledge of local climate, topography, and soils aids in recognizing sheet erosion and gulying on aerial photographs.

Figure 37.—Six drainage patterns.

ASCS—BRG-1E-184; BRG-1E-185

Figure 39.—This stereoscopic pair of an area in Texas provide an excellent example of how erosion appears on photographs. Sheet erosion registers as light and very light areas with diffuse edges and gullies as white networks of long scars with irregular borders. Gullies and stream channels from weakly developed to deep and U-shaped are readily recognized under a stereoscope.

SCALE 1:20,000

NA—CCO-203-42; CCO-203-43

Figure 40.—These photographs show eroded soils and complexes of solodized-Solonetz soils and Chestnut soils from shales in southwestern North Dakota. Light tones that have diffuse borders represent eroded Lithosols or thin weakly developed Chestnut soils. The complex shows a reticulate pattern of light and dark, particularly in the upper parts of the photographs.

Sheet erosion may register in tonal differences and light patches. Seriously eroded areas not covered by vegetation photograph light (figs. 39 and 55). Light tones, however, are not always indications of sheet erosion. The soil scientist takes into account that steeply sloping soils are more likely to erode than those gently sloping, that in areas of subdued relief erosion is likely to occur at the crests of low ridges, and that eroded areas may be covered by crops or native vegetation. He applies his knowledge of plant succession and his ability to recognize different kinds of vegetation on aerial photographs. For example, where the climax vegetation is hardwoods, patches of young pines may mark eroded areas that have been abandoned and are revegetating.

Gullies appear as long scars with definite irregular borders (fig. 39); they contrast with sheet-eroded areas, which have more diffuse and smoother outlines (fig. 27). Gullies are common in natural drainageways and at the boundaries of fields.

Certain characteristics of gullies are related to soils (fig. 41). The gradient and cross section may indicate the kind of parent rock and the soil texture.

Gullies in well-drained sandy soils are V-shaped in cross section and have steep gradients; those in poorly drained fine-textured soils are apt to be saucer shaped in cross section and to have gentle gradients. Gullies in stratified soils have irregular side slopes and abrupt changes in gradient.

Vegetation.—Vegetation is identified on a single photograph mostly by tone, but some that cannot be distinguished by tone alone can be through a stereoscope. Prairies, forests, and cultivated fields are distinct on single photographs (fig. 42). Forest and nonforest, deciduous and coniferous trees, and young and mature growth generally can be distinguished by tone. Many foresters can identify dominant species in forest types by comparing heights of trees and sizes and shapes of crowns. By comparing the image of trees on the photograph with trees in the forest, the soil scientist improves his ability to identify kinds of tree cover.

The appearance of vegetation changes with the season. Deciduous trees photographed in winter have a lacy appearance and a lighter tone than that of coniferous trees.

Tall, short, and mixed grasses are difficult to distinguish from each other even in large areas of native vegetation. Sparse desert vegetation is easier to recognize.

To identify vegetation, the soil scientist should be familiar with plants in the area and their relation to the environment. A knowledge of plant succession furnishes clues helpful in identifying soils.

IDENTIFICATION OF MANMADE OBJECTS

Since manmade objects have sharp boundaries they are generally easier to recognize on aerial photographs than are natural features, and they are also more emphasized than natural features on stereoscopic pairs.

Farm Forests, Fields, and Orchards.—From manifestations of tone, the photo interpreter can tell how land is used. Forested areas appear mottled (fig. 20). Fields can be identified by their distinct boundaries and their patterns of dark and light (fig. 43). Harvested crops of hay, small grains, and corn in shocks can be identified by regularly spaced dark spots. Orchards have a more open pattern of larger spots. Terraced fields and stripcropping have alternate light and dark strips.

The arrangement, size, and shape of fields vary according to the type of agriculture. Fields are larger and more uniformly spaced in dry-farming areas than in humid areas. Field boundaries may appear as straight lines between patches of contrasting tone. The dark tones of hedgerows and other vegetation often

Figure 41.—Typical gully characteristics.

Figure 43.—The scattered light spots on these photographs of dry-farmed tablelands in Nebraska represent thin soils in residuum from siltstone and sandstone; the dark background represents deep and moderately deep Chestnut soils in loess. Outlining the bases of the low ridges or knobs under a stereoscope shows the abrupt and wavy boundary between the soils in loess and those in residuum.

SCALE 1:20,000

SCS—DSF-2L-186; DSF-2L-185

Figure 44.—These photographs of an area in Georgia illustrate the contrast in appearance of mineral soils and organic soils under cultivation. The very light gray areas marked A represent Low-Humic Gley soils intergrading to young marine clays of the salt-water marsh. The dark-gray or black areas marked B suggest organic soils. Hedgerows produce the very dark irregular lines along field boundaries.

mark boundaries and fences (fig. 44), but generally the photographic scale is too small to show fences.

Buildings.—Buildings can be recognized by their angular shapes and contrasting tones. The part of the roof directly exposed to the sun photographs light and contrasts sharply with the shadow cast by the building. Farm buildings are usually in small rectangular groups beside or at the end of roads. In the arid southwest they are isolated; in the Great Plains they may be in groves of trees or among scattered trees; in the dissected or mountainous section of the humid Southeast they may be in cleared patches surrounded by forest.

Roads, Trails, and Streets.—Roads and trails commonly photograph as light lines. Improved roads have uniform width, straight stretches, and smooth, gentle curves; unimproved roads are more irregular in width and have sharper curves. Large uniform squares bounded by roads suggest sectionized rural areas, clusters of small rectangles indicate towns or cities (fig. 26).

Railroads.—Compared to roads, railroads are narrower, have longer and smoother curves, and are darker on aerial photographs. Along the right-of-way large cuts and fills, spurs, stations, and warehouses can be detected.

Bridges.—Bridges can be located by following the course of a road or a railroad until it crosses a stream or by following a stream and noting the interruption of tone caused by the

bridge. The kind of bridge can often be identified from its shadow.

Tunnels.—Tunnels can be identified by the dark spots of their portals, by the spoil near the portals, and by the sharp termination of the road, railroad, or canal.

Power Transmission Lines.—Transmission lines are difficult to detect in open areas on some photographs used in soil surveys. On photographs of very large scale, towers or their shadows can be seen. In wooded areas, power lines are long, narrow, cleared stretches that have angular changes in direction rather than curved changes.

IDENTIFICATION ON PHOTOGRAPHS TAKEN AT DIFFERENT TIMES

By comparing photographs of the same area taken several years apart, the extent and rate of erosion, especially gully and streambank erosion, can be estimated. The meandering of streams can be traced, and changes in land use noted. Damage from range and forest fires can be assessed.

Pictures taken before and after floods are often used to appraise flood damage. "Before" and "after" pictures also indicate changes caused by the construction of a large dam and by the filling of the reservoir that is formed. The extent of the encroachment of urban development, highway construction, or powerline installation on agricultural land can be estimated. During periods of drought or draw-down, sedimentation studies can be made.

INFERENCES FROM FEATURES IDENTIFIED

To make reliable inferences the soil scientist must correlate features on the aerial photograph with soil characteristics observed in the field. A knowledge of soil genesis, especially as it relates to geomorphology, assists in understanding correlations made in the field. A person who is well versed in the phases of soil science and who has a good understanding of the soils in the area studied can obtain much more from aerial photographs than one less well versed.

SOIL DIFFERENCES

Some differences among soils can be detected from variations in tone on the aerial photograph; some can be inferred from analysis of surface features that reflect soil differences.

Clues to these differences are found in such features as landforms, stream dissection, drainage networks, vegetation, and land use. Combinations of these features may coincide with the morphological characteristics used in separating soil classes such as great soil groups or soil series. Thus, soils on uplands that have distinct horizons may be distinguished from alluvial soils with faint or no horizons on flood plains. Poorly drained soils appearing dark in depressions may be set apart from well-drained soils on convex slopes (fig. 45). Several morphological features and chemical properties are neither expressed nor implied by features apparent on an aerial photograph. These can be

SCALE 1:20,000

Figure 45.—The mottled dark-gray to black pattern against a lighter background represents an association of Chernozems and Humic-Gley soils on the till plain of North Dakota. Humic-Gley soils, which photograph dark, are in the small closed morainic depressions; Chernozems in the light intervening areas.

distinguished only by field investigation or perhaps laboratory analysis.

Differences in tone that give clues to differences in soil can be seen in figures 32, 46, 47, and 48. Differences in tone, however, do not always indicate significant differences in soil, and differences in soil are not always revealed by differences in tone (fig. 49). The soil scientist must be able to distinguish change in tone caused by the angle of reflected light from that caused by some feature on the ground. The best way for him to prevent errors in identification and inference is to work out the local relationship between the landscape and the patterns on the photograph.

Dark-colored soils are dark toned on the photographs and light-colored soils are light toned (fig. 50). A lightening of tone usually indicates better natural drainage of the soils, stronger slope, more severe erosion, or coarser texture. A light-toned area, however, may be a poorly drained soil covered by a light film of water when photographed. On the other hand, dark-toned areas may be from soil plowed shortly before the photograph was taken.

In many places, differences in landform and drainage patterns indicate broad differences in soils and their parent materials. Experienced field soil scientists recognize bottom lands, terraces, alluvial fans, upland plains, hills, and mountains on aerial photographs of most regions. Generally, soil and slope boundaries coincide with boundaries of landforms and can be accurately located on aerial photographs. The soil scientist must remember, however, that many of the boundaries highly significant to accurate soil classification and mapping are not related to landforms.

Patterns are often misleading, and interpretations are found to be incorrect when the soils are examined in the field (fig. 51). Patterns that appear the same may represent unlike landscapes or associations of soils. Color patterns may be associations of eroded and uneroded soils, coarse- and fine-textured soils, well-drained and imperfectly drained soils, and other combinations. The soil scientist who is aware of these possibilities will determine which are most likely through both field examination and photo interpretation.

If it can be determined from an aerial photograph, the type of vegetation cover may indicate

what kind of soil to look for and where to look. In some areas rather consistent correlations of vegetation and soil can be made; in others the probable correlations are few. In a dominantly agricultural area, one would expect soils in a patch of woods to be different from soils that have been cultivated for a long time. But in some areas aerial photographs of vegetation do not reflect soil characteristics that would be important if the soil were cultivated (fig. 52).

Fires modify vegetation without immediately affecting the soil. Also, clues that show on one photograph may be masked by vegetation on another. This makes it necessary to work out the relationship between elements of the landscape and the pattern on the photograph by direct observation in the field.

Different patterns of native vegetation imply differences in soils. For example, concentric rings that progress from grasses and sedges to low bushes and trees as they extend outward from the borders of a pond indicate that the soils are increasingly better drained as the distance from the pond increases.

EXPRESSIONS OF FACTORS OF SOIL FORMATION

Relief and vegetation as they were at flight time can of course be seen on an aerial photograph. Preexisting relief and vegetation that had a profound influence on soil formation can only be inferred. This is true also of parent material, climate, and age of landforms.

Relief.—Relief changes slowly, and probably has changed very little from the earliest stages of soil formation up to the time the photograph was taken. Allowance must be made, however, for erosion and other changes brought on partly by the activities of man.

Vegetation.—To evaluate the relationship of vegetation and soil, the soil scientist should become familiar with local ecological environment, including plant succession. He can then compare present with past vegetation and determine whether the vegetation he identifies is representative of earlier types. The soil scientist will be aware, for example, of how the original forest was altered by burning or cutting.

Identification of native vegetation may lead to inferences about soil and soil genesis. Pine forests in Maine, northern New York, and Michigan are clues to Podzols or to the formation of Podzols. Mixed deciduous and pine forests on

Figure 49.—Quite different soils may photograph in similar tones. Here a Reddish Chestnut soil in Texas in area A appears in light-gray tone like that of the Calcisol in area B. The darker tones of soil 34f, also a Calcisol, are as dark as those of soil 34, which is a Grumusol.

SCALE 1:20,000

NA—AWW-7-84; AWW-7-85

Figure 50.—These photographs of an area underlain by chalk in Texas illustrate the relationship of light and dark tones to differences in color among soils. Dark tones represent nearly level or gently sloping Grumusols, which have thick dark surface horizons. Light tones portray more strongly sloping and light-colored Lithosols formed in residuum from very light gray or white chalk. The topographic expression, though moderate, is easily noted under a stereoscope.

SCALE 1:31,680

USAD—TM-14-162

Figure 51.—In this photograph of an area in New Mexico the pattern suggests a rough, choppy, complex landscape with no agricultural potential except for range. Field examination, however, showed a succession of miniature escarpments 6 inches to 3 feet high on an alluvial fan; the escarpments are topped by ridges of sandy Regosols in eolian deposits 6 to 24 inches thick. Regosols are moderately fine-textured soils formed in alluvium.

SCALE 1:13,000

LEFT, USAF—4M741—4V—25, RIGHT: ASCS—AXL—44K—7

Figure 52.—These photographs of an area in the Mojave Desert, Calif., show vegetation that fails to reveal important differences in soil characteristics. The uniform cover in the left photograph consists chiefly of ereosotebush and bursage. The same 160-acre field is shown on the right after leveling and planting to alfalfa. The light streaks represent narrow beds of gravel or ebbles, which affect the efficiency of irrigation but have no apparent effect on native vegetation.

rolling or hilly uplands in the Southeast are related to the formation of Red-Yellow Podzolic soils. In the northern Great Plains tall grass was the native cover over Chernozems when they were forming.

Parent Material.—Parent material can be inferred from the aerial photograph after considering the landforms and, in some areas, the vegetation. But such inferences may be unreliable because no specific kind of parent material can be correlated exclusively with a specific kind of landform or vegetation. Rock structure, climate, and other factors affect the relationship.

In some areas, however, relationship can be found between topography shown on the photograph and parent material. In the Appalachian Highland, for example, rolling limestone valleys and ridges are distinct from steeply dissected shale plains; these in turn are unlike mountainous areas of crystalline rocks. In central United States, rolling areas of thick deposits may be separated from adjacent driftless plateaus that are more dissected.

Climate.—The climate of an area is reflected in the shape of landforms and in stream patterns, but the most reliable key to climate is vegetation. The effect of climate on vegetation can be seen by comparing vegetation across the United States; vegetative zones correspond to broad climatic belts.

The relationship of soils, climate, and vegetation in the western part of the Central Lowlands is also striking. Gray-Brown Podzolic soils occur in the humid, forested valleys; Brunizems are on the less humid grassland divides that intervene.

Age of Landforms.—Inferences concerning the age of landforms of an area, at best very general, are based mostly on deductions made after studying the physiographic expressions and acquiring some knowledge of the geology. Young soils are likely to occur on steep hillsides and flat flood plains. On strong slopes, horizon differentiation hardly keeps pace with geologic erosion. On alluvial plains, continued accretion of fresh materials keeps the soils young.

PLANNING FOR THE DETAILED SOIL SURVEY

Aerial photographs are used in both detailed and reconnaissance soil surveys. The principles of photo interpretation are the same for both although applications of them differ somewhat. More reliance is placed on clues offered by the photographs in reconnaissance than in detailed soil surveys. This is true of both determinations of kinds of soil and placement of soil boundaries. In detailed soil surveys, field examinations are made at frequent intervals and boundaries are observed throughout their entire course. In reconnaissance soil surveys, field examinations are widely spaced and parts of soil boundaries are projected.

Most soil surveys are detailed and procedures have been developed for the use of aerial photographs in such surveys. These procedures are outlined in this section. They include evaluations of existing aerial photographs, judgments of the need for procuring new ones, day-to-day operations, and determinations of the relationships of photographic features to elements of the local landscape.

PROCUREMENT OF AERIAL PHOTOGRAPHS

Plans for procuring aerial photographs should be made about 2 years before the start of a soil survey.

The SCS Cartographic Division prepares a report of existing aerial photography, which includes other agencies' plans to fly the survey area in the immediate future. On the basis of the report, and on knowledge of the physiographic changes since the last aerial survey, the SCS State Conservationist through his soil scientist decides whether a new aerial survey is needed.

If it is needed, arrangements to initiate flight operations must be made at least 1 year before the photographs are needed in the field. Aerial surveys are made by commercial aerial photographers under contract. About 6 weeks should be allowed to develop the specifications and schedule of advertisement, prepare flight maps, solicit bids, and award the contract.

If the State Conservationist decides that the existing aerial survey is adequate, photographs

are obtained through the Cartographic Division. Most soil surveys are made on photographs enlarged to scale 1 inch=1,320 feet (4 inches=1 mile). Where large-scale irrigation or land leveling developments are contemplated, more detailed soils information may be needed than can be shown at a scale of 1 inch=1,320 feet, and larger scale photographs are required. Contact prints, being of smaller scale, often are helpful in making a stereoscopic study of the area because a larger area can be viewed at one setting. Also, the smaller scale concentrates the detail, and broad associations of features can be studied.

Unless an older survey is specified the Cartographic Division furnishes photographs from the most recent adequate aerial survey. Photographs should be examined immediately to see that they are good quality prints and that all prints needed have been received. Images on the photographs should be sharp to permit study of small details. Prints should be of normal contrast with shadows and highlights printed so that details of the negatives reproduce to maximum advantage.

SELECTION OF PHOTOGRAPHS

Ordinarily, soil-survey data are recorded on alternate photographs since this reduces matching delineations of soils and other features from one photograph to the next. It also reduces costs of reproducing the completed soil-survey field sheets since only half as many sheets are required. But for areas of rough terrain, where the difference in ground elevation exceeds 750 feet on a large part of the survey area, soil-survey data are recorded on every photograph. Where there are large blocks of different terrain every photograph is used for the mountainous part and alternate photographs for the less rugged terrain.

COLLECTION OF REFERENCE MATERIAL

In addition to aerial photographs, existing maps and reports of the survey area should be studied. Photoindex, topographic, geologic, and forest-type maps, old soil maps and reports, and planning board maps and reports are helpful.

PROCEDURES FOR USING PHOTO INTERPRETATION IN MAKING SOIL SURVEYS

USE OF PHOTOINDEX SHEETS

Photoindex sheets are generally at a scale of 1:63,360 (1 inch=1 mile). Since each sheet covers a large area, they may show overall geologic and soils relationships not readily seen on individual photographs. Photoindex sheets are also useful as a base for the preparation of a preliminary soil-association map. Such a map is helpful in setting up the standard soil survey legend.

Photographs of representative sections of the areas should be selected from the index sheets. These should be studied stereoscopically to acquaint one with general topography, landforms, erosion, drainage patterns, land use, and general appearance of vegetation. Later, they should be checked in the field to determine the range and meaning of tone and to learn the local causes of differences in tone, such as wetness, soil texture, vegetation, bedrock, and outcrops.

MATCH LINES

Before the soil survey is started, match lines are drawn on every photograph selected for delineation of soils data. These lines are boundaries of the area to be mapped on the photograph. They can be drawn with or without the aid of a stereoscope. In using the stereoscopic method, a straight line is drawn midway through the overlap area parallel with the photograph edge. The straight line is then stereoscopically transferred to the adjoining photograph (fig. 53). In rough or mountainous terrain this line is usually transferred by marking its location on the high points, or ridges, and on the low points, or bottom drainage, and connecting these points by a series of straight lines. In areas of rough terrain, a straight match line on one photograph will be a very irregular one when transferred to the adjacent photograph.

Straight match lines can be transferred without using a stereoscope by sketching the line where it seems to curve over high spots and through low spots. On flat land the match lines may be transferred by connecting the same points of detail with a straight line.

In both methods, the process is continued

throughout the survey area by transferring the match lines to the next photograph in the flight line and to adjacent photographs in the adjoining flight lines.

Match lines may follow prominent ground features, such as roads, railroads, rivers, or land lines. If cultural and physical features are concentrated along the road, the match line should be drawn where it would be less difficult to match delineations of soils and other features. Match lines are usually drawn with green pencil.

STEREOSCOPIC REVIEW

A careful stereoscopic review should be made each day before starting work. First, the area to be surveyed should be determined. If this is a farm or ranch its boundaries should be delineated on the photographs. With a stereoscope, the area is scanned to make a brief mental review of significant conditions such as type of farming, topography, geology, landforms, soils to be expected, drainage conditions; and farming practices.

PRELIMINARY DELINEATION OF FEATURES

Before field work begins all important features that can be accurately identified in the office should be delineated on the photographs. Some can be determined with more certainty than others, depending on one's familiarity with local conditions and skill with a stereoscope. Features easily identified should be delineated first. Then features that relate to and help identify obscure features should be studied. The following is an outline of steps for this preliminary stereoscopic delineation:

1. Major drains, smaller drains, intermittent streams, and drainage heads and ponds should be tentatively delineated before going to the field. This should be done in blue pencil so needed changes can be made after field checking.
2. If soil surveys have been made on adjacent photographs, all soil and mapped features should be transferred stereoscopically to the outside edge of the match lines. Many boundaries between kinds of soils, including slope and erosion phases, can be tentatively extended or closed. If

SCALE 1:20,000

SCS—DDS-192; DDS-1-93

Figure 53.—Transferred match line.

possible, lines should not be closed off directly on the match line. Careful selection of match lines minimizes the need for this.

3. Roads may be inked and classified on the basis of knowledge of the area and the latest county highway maps. According to some State policies, highways prominent and readily identified on a photograph need not be inked.

4. Whenever they can be identified, dwellings and other pertinent buildings outside of built-up areas may be inked on the photographs. In built-up areas, only public buildings important to farmers or farm programs such as court-houses and schools should be indicated

5. The following should be tentatively delineated in pencil:

- Bottom land and flood deposits

- Stream terraces

- Gravel and borrow pits

- Ridge lines

- Sinkholes and wet spots

- Swamp or marsh boundaries

- Other significant landforms such as escarpments and rock outcrops.

6. All slopes that are clearly seen and appear to correspond with the slope phases in the legend should be delineated, and the estimated slope groups given. In many soil survey areas, the definitions of slope phases vary among kinds of soil. Beginners may have difficulty delineating slope groups with reasonable accuracy. Regardless of the lack of success, this should be done and checked in the field each day, for this skill can be developed only through continual practice and field comparisons.

7. Gullied and severely eroded areas should be

delineated and an estimated-erosion symbol placed in the delineation.

8. Soil series or types that can be differentiated may be tentatively delineated and indicated by symbols.

9. Routes for traversing the area most efficiently should be planned. This should insure sufficient field checking and, at the same time, reduce the number of unnecessary traverses.

DETERMINATION OF GUIDES AND RELATIONSHIPS

Stereoscopic interpretations made in the office should be reviewed in the field and verified or revised as necessary. Areas not correctly identified in the office should be restudied. Valuable experience is gained by making notes on the relation of soil to the photographic features that are indicators of the particular soil. Accuracy in making estimates increases, and the soil scientist learns which delineations he can make with suitable accuracy.

For each slope group or major landform, slope can be established with an Abney level and areas delineated in the field. These delineated areas serve as references to compare with similar-appearing areas delineated with a stereoscope.

Soils tend to occur in systematic patterns. Assistance in determining local patterns may be obtained from the study of topographic and geological maps and reports. Block diagrams showing the relationship between local soil types and phases need to be prepared. (See figures 59 and 62.) These diagrams help to visualize the relationships between kinds of soil areas and factors that pertain to the development and occurrence of soils in the landscape.

CORRELATING AERIAL PHOTOGRAPHIC IMAGES WITH SOILS IN SPECIFIC AREAS

In many places soil scientists have learned how to recognize distinctive soil landscapes or soil associations on aerial photographs. Though within a given landscape the boundaries between soils of strongly contrasting texture, drainage, or depth can be readily recognized, this is not true of finer distinctions among these features. The soil scientist needs to be thoroughly familiar with soil landscapes on the ground before he attempts to interpret soils from the aerial photographs.

Up to now, no systematic key correlating aerial photographic images and soils has been issued. But soil scientists have used photographic tone, pattern and kinds of vegetation expressed in photographic tone, and physiography as interpreted from tone, detail, patterns, and shadows to make their own correlations.

The following extracts of local correlations are mainly from the humid East. With them as guides to things to look for in aerial photographs, each soil scientist should develop his own local key. Using such keys can significantly accelerate soil-survey field work.

CORRELATIONS IN THE NORTHEAST

Connecticut.—Landforms such as traprock ridges, drumlins, ground moraines, glaciofluvial or outwash terraces, kame and kettle topography, eskers, lacustrine terraces, flood plains, and bogs are features that can be identified with a stereoscope. Soil associations with well-defined features are associated with each of these landforms. Soil features such as drainage, texture, degrees of stoniness, and kind of vegetation can also be interpreted to a certain degree with a stereoscope.

Shallow to bedrock soils are common on traprock ridges in the Connecticut Valley of Connecticut. The principal indications of traprock ridges are steep western slopes that have dark tones due to shadows and linear crests that are jagged, irregular, and sharply outlined. The adjacent areas to the east have uniform decreasing slopes. There are more hemlock trees, recognizable by dark images, than on adjacent associated shallow soils. Presence of hemlock itself, however, does not indicate traprock ridges.

Shallow soils on granite, gneiss, and schist,

usually appear as large domelike rounded hills irregular in topographic features. The drainage pattern is dendritic; typical curved lines emerge from the base of the hills. Scattered light patches indicate exposed bedrock and a surrounding mantle of shallow soils. Darker tones are more difficult to interpret because of the nature of the topography, vegetation, and bedrock reflections. Extensive dark tones on either side of streams suggest soils with restricted drainage. Natural vegetation—mainly oak, maple, and beech and scattered white pine and hemlock—appears medium gray with some dark spots.

Drainage patterns of moraines, which have irregular slopes in contrast to the long, uniform, contoured slopes of drumlins, lack uniformity because of the irregular topography. There are many small individual drainage patterns that do not combine to form a well-defined drainage system. Individual streams are not long but are well defined. Generally they empty into peat bogs, swamps, and ponds in the low points of the landscape.

Light gray tones of moraines usually indicate shallow soils on steep valley walls or hillsides. Medium gray tones are confined to 3- to 8-percent slopes, which generally are moderately well drained. Darker tones on 2- to 3-percent slopes are evidence of poorly or very poorly drained soils. In general, all cultivated areas have the same tone. Oak, maple, and beech, the principal tree species of a mixed hardwood cover, appear in fairly uniform gray tones.

Drumlins, generally oriented in a northwest to southeast direction in Connecticut, are smooth, oval, cigar-shaped hills. A few, which are broad, flat surfaced, short sloped, and less elongated than typical, appear semicircular to semioval. Though defined drainage patterns are lacking, they do control the drainage in many adjacent till-covered areas. Those with broad tops or semioval shapes usually bear intermittent streams that flow southeast, that is, with the long axis.

Since many drumlins have soils with impervious subsurface layers that restrict vertical movement of water, lateral movement of water on the long slopes results in occasional seepage

spots and these are conspicuous by their darker tone. A uniform gray tone indicates moderate drainage and darker grays poor drainage. Clean-tilled land is usually lighter toned than old pastures and hayfields, but in both differences in soil drainage are reflected by tone.

Glaciofluvial and outwash terraces, generally nearly level to undulating, in places occur as a series of benches with intervening short terrace escarpments. Lack of surface drainage patterns show that the subsoil and substratum are permeable. Rapid permeability also accounts for the typical, but occasional, V-shaped short steep gullies. Light to bright overall tones are characteristic of terraces. The lightest tones indicate well-drained coarse-textured soils; darker tones indicate somewhat poorly drained or poorly drained finer textured soils.

Eskers, which are long narrow steep winding ridges consisting of sorted gravel and sand deposited by glacial-melt waters flowing in ice-walled tunnels or channels, appear superimposed upon surrounding landforms. Photographic tone as such is not diagnostic for eskers because gullies are few and the esker tones blend with surrounding landforms. When examined under the stereoscope, however, they stand out as ridges. Some show gravel pits. In many places they are idle or in forest in contrast to adjoining areas of outwash or till in cropland.

Kames and kettles are individual knobs or linked knobs with irregular shapes and haphazard distribution interspersed with random shallow to deep depressions and no definite drainage patterns. Coarse texture accounts for white-toned V-shaped gullies that occur on steep-sloped mounds. Tones range from white to light gray on kame crests and to darker shades toward the slope bases. Intermittent spattering of white to gray photographic tone, coupled with the topographic features, gives a three-dimensional effect on some single photographs. These topographic features are readily recognized under the stereoscope.

Though lacustrine deposits are distinct from the surrounding landforms, the topography may be so similar to adjoining areas of glacial till or outwash that differences are not discernible under the stereoscope.

On undulating topography, silts and clays generally lack well-defined drainage or gully patterns. Bright, dark gray, and random tones

within a specific area are typical on these materials. Low mounds of sands are bright and are usually pock marked with black depressions. Clays, moderately well to poorly drained, have uniform light gray to darker gray tones.

Clay and sand over clay in terrace positions commonly have a fine dendritic drainage pattern. The valley walls are V-shaped and steep; interfluves are narrow and rolling. Photographic tones are fairly uniform except for shadows cast by the slopes. Gray tones are typical for the moderately well drained soils. The gray tone and drainage patterns are the principal indications of clay soils on dissected landscapes. In many places, undulating to rolling slopes can be delineated from hilly and steep areas under a stereoscope.

An overall level surface is the most significant feature of flood plains. Along mature rivers this uniform slope may be broken by irregularities which result from local stream cutting and deposition. Sandbars appear as raised areas adjacent to or parallel to rivers. Though uniform drainage systems do not develop on flood plains because of their low position, seasonal flooding, and deposition, streams flowing from the surrounding topography cut across flood plains in some places. Black streaks—curved and generally parallel—are typical of channel scars, oxbows, and abandoned channels. The black tone is accounted for by the fine-textured mineral soils and organic matter that accumulate in these depressed areas. Linear streaks of well-drained sands or loamy sands appear as nearly white. The gray tones represent level areas with a high water table.

Peat bogs usually occur as depressions; streams are very few. Vegetation changes abruptly at the border between the bog and surrounding terrain. Photographic tones are distinctly darker than surrounding areas.

In many places bogs are covered by low brush, sedges, and moss; these areas appear as a smooth gray tone. At higher elevations some bogs covered by spruce forest appear dark gray to nearly black in contrast to the lighter gray of adjacent uplands covered by hardwoods. Some of these bogs have a rim of spruce which diminish in height and give way to brush toward the center. Regardless of kind of vegetation, nearly all bogs are darker toned than adjoining better drained areas.

SCALE 1:20,000

NA—CXE-3B-147; CXE-3B-148

Figure 54.—These photographs represent the gently to moderately sloping landscape of ground moraines of Wisconsin glaciation in New York. Well-drained Gray-Brown Podzolic soils are on the gentle rises and Planosols and Low-Humic Gley soils on lower slopes and in depressions.

New York.—In New York, main soil associations can be recognized by tone although many associations may have similar patterns. In many places the soils can be picked out by photographic tone, shading, or vegetation.

Large areas of outwash photograph either in light or very light tones on level plains or in the spattered pattern of kame and kettle topography. Sharp slopes breaking to the bottom lands or valley sides usually can be recognized by slightly darker tones but are best identified under a stereoscope. Where frost-moved material covers the outwash, the slope to the valley sides is gentle and difficult to identify except under a stereoscope.

Where present in large blocks soils from lacustrine material usually have recognizable patterns. They have gently undulating to moderately steep topography.

Where the topography is nearly level, tonal value is the most important photographic feature for identifying individual soils that differ in drainage. Light gray tones are registered by Vergennes soils which have the best drainage, intermediate gray by Panton soils, and dark gray to black by Livingston and Covington soils, which have the poorest drainage. Limestone outcrops associated with these soils appear as light toned streaks or spots.

In areas that are dominantly till, the gently to moderately sloping landscape without abrupt slope breaks usually denotes deep, moderately well and somewhat poorly drained soils (fig. 54). Steeper slopes usually include well-drained soils. Darker toned depressions contain poorly and very poorly drained associates.

In the southern tier (Allegheny Plateau) Lordstown soils usually can be identified by step-like relief with short, steep breaks along a general east-west axis. The breaks are interspersed with nearly level to gentle slopes. Where this relief is absent the Lordstown soils may be mistaken for Bath, Mardin, or Volusia soils on photographs. Shallow soils do not give consistent tone values; field examination is necessary to differentiate them.

Shallow and moderately shallow Nassau and Macomber soils on folded rocks along the Hudson Valley are identified by the pattern of short broken slopes along a general north-northeast to south-southwest axis. Deeper Cossayuna and Dutchess soils on drumlins can be distin-

guished by their long uniform slopes. Poorly and very poorly drained soils of local alluvium in depressions and soils in glacial lacustrine materials appear in darker tones but are difficult to distinguish from each other without field checks.

In Rensselaer County the pattern of complexes of deep and shallow soils over folded bedrock, with occasional rock outcroppings, generally shows up well especially in areas that have been plowed or are in cultivation. On the newly plowed land, the outcrops and shallow areas are darker toned; in areas under cultivation, these same areas may be lighter toned than the surrounding land.

CORRELATIONS IN THE SOUTHEAST

Tennessee.—In Tennessee, most major soil associations in the Red-Yellow Podzolic soil region have slightly different tone patterns. A few, however, appear similar even though the soils of each are different.

The Dandridge-Whitesburg-Lindside soil association presents the most distinct pattern. The deeply entrenched drainways, high dissection, steep relief, and large amount of forest all show clearly on the photograph. Tones and other clues help identify the individual soils within the association. Ordinarily these clues suggest two or three soil series rather than clearly pointing out a specific one. After the soil scientist has identified the soil in the field, he usually can interpret area boundaries from the photograph. For example, Whitesburg soils on local alluvium are dark toned on the photograph because of higher moisture content and dense vegetation. On narrow strips of bottom land, however, Lindside and Melvin soils also photograph as dark areas.

In the Litz-Sequoia-Lindside soil association, also derived from shales, the landscape is dominantly rolling and hilly and streams are not so deeply entrenched. Individual fields are small; many areas are severely eroded and covered with second-growth pine forest. These clues suggest small subsistence farms and soils of low fertility and high susceptibility to erosion. Badly eroded areas within the association suggest either gullied land or severely eroded Litz soils. Where areas are nearly bare of vegetation, erosion can be detected on the photograph by light tones; where areas are covered by pine

forest, erosion can be detected by almost black tones. Most soils on local alluvium and narrow bottom land appear in dark tones. Once specifically identified with an auger, most areas can be delineated by differences in tone. Many soils on uplands and old colluvial slopes are similar in photographic tone and little photo interpretation of soils can be made.

In the Dewey-Decatur-Emory soil association, underlain by materials weathered from dolomitic limestone, fields are larger and more regular in outline; more land is in cultivation and crops; and only small areas are severely eroded. These features indicate that soils are higher in fertility. A poorly defined drainage pattern, modified by many sinks and depressions, can be fairly well detected. Small round depressions show as dark areas because alluvium high in organic matter covers the floors of the depressions. Numerous depressions indicate an irregular karst topography.

In many places studying photographs under a stereoscope is the quickest and most accurate means of locating sinkholes, especially in wooded areas. Mottled light and dark tones in this association indicate an uneven erosion pattern; the light spots have lost their original surface layer and the exposed dark red subsoil reflects a light tone on the photograph either because of bright color or sparse vegetation. (Almost all aerial photograph film is highly red sensitive.)

Most local alluvial areas contrast with upland soils by dark tone. Dewey and Decatur soils on the uplands cannot be separated by photo interpretation.

The Muskingum-Jefferson association is characterized by the narrow linear shape of its individual ridges and intervening valleys and the ridges are conspicuous on the photograph. Photo interpretation is of limited value in identifying soils in the intervening valleys; the valley floors are irregularly covered by alluvial and colluvial materials. Local alluvial spots are clearly shown by darker tone.

In East Tennessee, areas of Tellico soils, derived from the Holston formation, stand out in high ridges and are readily distinguished from soils derived from lower lying limestone and shale formations. Also, Lebew soils on the knobby or comby ridges of the Rome formation can be distinguished from lower lying soils on limestone, such as Dewey soils.

In the dissected area adjoining Caney Fork River in DeKalb and Warren Counties, the soil association comprises steep, forested Bodine soils capped by Mountview, Bodine, or Waynesboro soils in open land. Bodine and Mountview soils, which are moderately eroded, appear medium gray. Waynesboro soils, usually severely eroded and often gullied, appear in much lighter tones.

In areas of uniformly dissected landscapes, such as Bodine-Mountview-Lobelville association (fig. 55) or Memphis-Collins association, the soil scientist can make field checks at much wider intervals if he separates ridge tops and bottom lands under a stereoscope before going to the field.

Two landscapes in Tennessee that appear similar on photographs despite major difference in soils are the Highland Rim Plateau (open land Dickson and forested Guthrie soils) and the Inner Basin (open-land Hagerstown and Talbott and forested rockland areas).

Two that appear similar on aerial photographs but have quite different soils are the Highland Rim (open-land Mountview and forested Bodine and Baxter) and the Cumberland Plateau (open-land Hartsells and forested Muskingum).

Well-drained bottom-land soils such as Pope and Huntington appear in light tones; poorly drained Melvin and Atkins appear much darker. The poorly drained soils may also be covered with forest or brush—another clue to their identification. Moderately well drained Lindsay and Philo soils are less easily recognized; they may be either dark or light. Areas of sandy soils appear as very light streaks. The first bottoms and low terraces of large stream valleys are commonly separated by short steep escarpments which show plainly on the photograph. Boundaries between soils on terraces are less clear, however, than between those on bottom lands.

In nearly all landscapes, stony and rocky areas appear lighter than the surrounding areas. The strike or banding of the rock is very evident.

Coastal Plains of the Southeast.—Much of the lower Coastal Plain in the Southeast has slight relief. Tone, kind and pattern of vegetation, and pattern of cultural features, however, are useful guides on aerial photographs to soil conditions in this area.

Vegetation does not reveal specifically the

Figure 55.—These photographs of a dissected limestone plateau in Tennessee illustrate the significance of photo interpretation in dissected areas of uniform bedrock. Regosols are on steep slopes, Red-Yellow Podzolic soils on drainage divides and high terrace benches, and Alluvial soils on flood plains. The white streaks with fuzzy edges in the cleared area represent soil erosion.

kind of soil, but it often gives an indication of what to look for and where to look. For example, in the sandhill section of the Southeast, scrub oak with scattered longleaf pine indicates well-drained deep sand, and pond pines and gallberry indicate wet sand. In the coastal flatwoods section, stunted pine indicates Ground-Water Podzols with hardpans such as Leon and St. Johns soils. In contrast the associated Plummer soils, which have no pan, support much heavier forest. Soil boundaries can often be accurately located by outlining areas of different vegetation on the photographs. In Bladen soils, pure stands of hardwood indicate fine-textured types, whereas mixed stands of pine and hardwood indicate sandy loam types. In poorly drained areas of the middle Coastal Plain, sweetgum is often an indicator of Coxville soils. Black gum is often an indicator of coarse-textured poorly drained soils.

Water-loving vegetation shows dark to very dark gray in tone; its area is irregular. Trees or water-loving vegetation in dark tones appearing as narrow bands with irregular curves are clues to stream channels. Cypress indicates very poorly drained soils; it can readily be distinguished from pines.

In Florida, differences in patterns of vegetation can help the soil scientist separate poorly drained soils on acid sands from those on neutral sands even though the soils are identical in color and are similar in overall tone on the photograph. In many places cabbage palms indicate neutral to slightly acid soils or soils with carbonates at moderate depths since pine trees grow on acid soils. The vegetation alerts soil scientists of the need to examine given sites for possible differences in reaction.

In many areas in the Atlantic Coastal Plain in the Southeast, tone or pattern on the photograph may give a direct clue to soil differences (figs. 22, 32, 33, and 47). For example, cleared well-drained sandy soils appear lighter than cleared well-drained fine-textured soils. In wooded areas the vegetation shows up darker on fine-textured soils. Poorly drained soils show up as dark areas in both wooded and cleared areas. Well-drained clayey soils generally are represented by gray tones on the photograph.

Tones are somewhat misleading, however, since they are influenced by vegetation on the

soil. Contrasting shades of light gray indicate coarse-textured somewhat excessively drained soils. Small irregularly shaped light-colored areas within darker areas may indicate severe sheet erosion. A disorderly arrangement of short lines in the direction of the slope represents gullies, which show up clearly under a stereoscope.

A boundary of gray tone against a dark gray tone implies a boundary between well drained and moderately well drained soils. As soil drainage becomes poorer, tones become darker. This suggests that there are two—and possibly three—soil series. In Florida, smooth dark gray tones often suggest Ona, Scranton, Sunniland, or Adamsville soils, whereas black or very dark gray are clues to Rutledge, Portsmouth, Plummer, Delray, Pompano, or Charlotte soils. The first group are moderately well drained and somewhat poorly drained soils, the second poorly drained and very poorly drained. Within the darker tone, areas of light gray sprinkled with black imply the presence of Leon, Pomello, or Immokalee soils, all of which are Ground-Water Podzols.

The boundary lines between better drained and more poorly drained soils on first bottoms can be recognized on aerial photographs because the more poorly drained soils commonly appear darker.

In Florida and Georgia, tone can give an accurate indication of major soil associations within an area. In many areas of Florida, tones give clues to areas having as few as two soil series. Within forested areas gray tones liberally sprinkled with spots of white indicate areas in which acid coarse-textured excessively drained soils predominate.

There is a danger, however, of misinterpreting this feature of a photograph. Coarse-textured excessively drained soils in some parts of Florida appear as dark gray or gray tones intermingled with specks of black that represent pines. This suggests soils that are influenced by limestone or phosphatic materials. In some areas dark-gray or gray tones on photographs represent clay soils. Smooth gray tones within the same area indicate a change in texture or the presence of soils with more restricted drainage. Increasing intensity of tone from gray to very dark gray strongly suggests somewhat

SCALE 1:20,000

ASCS—CDV-7M-174; CDV-7M-175

Figure 56.—Slight differences in tone and the pattern of drainage ditches often indicate differences in soil drainage. These photographs are of a truck-farming area in South Carolina. The light gray area (1) with scattered ditches irregular in length represents well-drained Red-Yellow Podzolic soils. The adjacent darker area (2) with many parallel ditches represents Low-Humic Gley soils.

poorly to very poorly drained mineral soils or soils with surface layers of high organic content (fig. 44).

Cultural and other features such as roads, ditches and canals, terraces, and field patterns may give useful clues to the kinds of soil to expect in some parts of the Coastal Plain (fig. 56).

In nearly level to gently sloping areas, fields are larger, field boundaries are more nearly straight, and secondary roads are straight in many places. Also, in contrast to more sloping areas that have smaller less regular fields and crooked secondary roads that are mainly in valleys or on ridge tops, terraces are lacking. Terraces, which are common on more sloping areas, appear as dark lines on the contour. The spacing of terraces is a clue to steepness of slope. Roads across better drained soils appear as light lines, those across lower more poorly drained areas as dark lines. None of these features by itself is necessarily diagnostic of a soil type, but the combination and patterns may enable the soil scientist familiar with the area to identify the soils.

Spacing of field ditches in truck-crop areas is a clue to the natural drainage and, to a lesser degree, to the subsoil texture of Humic Gley, Low-Humic Gley, and intergrades to Red-Yellow Podzolic soils on the first marine terrace of the Atlantic coast in Charleston County, S.C.

Ditches spaced 60 to 80 feet apart indicate poor to very poor drainage and a subsoil of plastic silty clay. Bladen and Bayboro are the principal soils having this close spacing. Somewhat wider spacing—80 to 120 feet—indicates poorly to somewhat poorly drained soils with subsoil textures ranging from sandy clay loam to sandy loam or loamy fine sand. Weston, Edisto, and Stono soils are the principal soils with these features. Wider spacing—more than 120 feet—and irregularly spaced ditches that are uneven in length indicate moderately well drained soils. These areas are better drained because they have slopes of 1 to 3 percent and are slightly higher than the surrounding soils. Eulonia and Charleston soils with subsoil textures ranging from sandy loam to sandy clay usually occupy these sites.

ACCURACY OF PHOTO INTERPRETATION IN SPECIFIC AREAS

Though photo interpretation is one of the most useful techniques in making soil surveys, too much or too little reliance on photo interpretation can result in inaccurate mapping. The objective is to use photo interpretation to maximum efficiency while keeping the mapping at or above acceptable standards of accuracy.

To obtain a better understanding of the accuracy that could be achieved through photo interpretation in specific areas, selected areas were interpreted and field checked by experienced soil scientists. The following are summaries of the procedures used and results obtained.

COASTAL PLAIN SAND HILLS OF SOUTH CAROLINA

A 640-acre area near Pontiac (Richland County), S.C., was outlined on aerial photographs. A soil scientist who had had 8 years' experience mapping soils in the area and who was thoroughly familiar with its geology and soil associations (fig. 57) and the vegetation that usually grows on the different soils made interpretations by using a stereoscope. He recorded his estimates of soil, slope, and erosion and placed soil boundary lines on the photograph in pencil. An inked tracing of these estimates was made on clear plastic as a permanent record (fig. 58). Then he and another soil scientist also familiar with these soils checked the estimates in the field.

His photo interpretation estimates were compared with the field mapping on the aerial photograph (fig. 59), by placing the inked overlay over the field sheet. The accuracy was determined by measuring the acreage on the overlay that did not correspond with the field mapping.

On 528 acres (82.5 percent), estimates by stereoscope were the same as the field mapping. All streams were accurately identified with the stereoscope. Of the 112 acres (17.5 percent) that were different, 38 acres were in error in designation of soil type or phase. One 12-acre area that was estimated to be Portsmouth sandy loam (53) on field examination was found to be Portsmouth loam (54). Identification of soil series and type was 94.1 percent correct. On

68 acres an error was made in estimating slope with the stereoscope. Two areas, totaling 44 acres, were a low B slope instead of the estimated A slope. Accuracy of estimating slope was 89.5 percent correct. On a 6-acre area class 2 erosion was not recognized.

The soil scientist using the stereoscope was not sure of the correct symbol to put in five delineations totaling 61 acres. He made first and second choices and placed a question mark by his second choice. These were recorded on the overlay before the field check. His first choice proved to be correct in three delineations totaling 36 acres. The second choice was correct on one 21-acre area. On one 4-acre area, the second choice was correct for soil type and erosion but the area was C slope instead of the estimated D slope.

The time required to map the 640 acres was as follows:

- $\frac{3}{4}$ hour in office making photo interpretation
- 5 hours in field checking the mapping done in the office
- $\frac{1}{4}$ hour inking time
- 6 hours—total time to map 640 acres (does not include travel time)

The block diagram in figure 57 shows the relationship of the major soils to the landscape and drainage. Clues used by the soil scientist in making his interpretations follow.

Figure 57.—Relationship of major soils to landscape in Coastal Plain sand hills of South Carolina.

ASCS—ATA-3H-138

Figure 58.—Estimates of soil, slope, and erosion delineated by a soil scientist using photo interpretation. Hatching indicates areas for which estimates made in the office were changed in the field. The area is in the Coastal Plain sand hills, Richland County, S.C.

Lakeland sand (18) occurs as dunes or hills on the highest elevation of the soil association. The tone of the photograph is light gray in wooded areas and nearly white in cultivated fields. Cultivated areas reflect so much light that field roads, furrows, and other minor culture tend to be obliterated. The scrub oak of the wooded areas is sparse, and the light gray sand between trees reflects a large amount of light. Minor trails show up very light. Scattered pines show up as dark specks. Under the stereoscope, slopes contrast readily.

Vaocluse sandy loam (96) contrasts markedly under the stereoscope with the associated Lakeland sand by showing a sharp and sudden break in slope. It usually occurs on slopes two or more classes higher and displays some characteristics of an escarpment. Many times it oc-

curs in areas shaped like a horseshoe. The associated thick surface phase (97) generally occurs in broader areas and on somewhat gentler slopes. Tone of Vaocluse sandy loam, thick surface phase, is lighter than Vaocluse sandy loam.

Vegetation on both types is denser and tone is a darker gray than on Lakeland sand. Pine thickets on formerly cleared areas show up black on the photograph. Vaocluse sandy loam often occurs as a narrow band at the highest part of the slope break and on breaks around stream heads. Streams frequently originate at the foot of these breaks.

Gilead sandy loam (115) contrasts with Lakeland and Vaocluse by being at the base of slopes—often in stream heads—and on gentle slopes along the major streams. Few areas are above C slope (6–10 percent). Tone of the pho-

Figure 60.—Delineations resulting from stereoscopic interpretations. The area is in the Atlantic Coastal Plain, Charleston County, S.C.

SOUTHEAST ATLANTIC COASTAL PLAIN OF SOUTH CAROLINA

Interpretations of the photograph of a 640-acre area on a first marine terrace in Charleston County, S.C., were made in the office by a soil scientist who had 12 years' experience mapping in this area. Delineations resulting from stereoscopic interpretations are shown in figure 60 and identified as follows: 1, Rutlege loamy fine sand; 2, Seabrook loamy fine sand; 3, Kiawah loamy fine sand; 4, Stono fine sandy loam; 5, Tidal marsh, high; 6, Tidal marsh; 7, Eustis fine sand.

For comparison, a plain photograph of this area is shown in figure 61. A block diagram of the relationship of major soils to landscape and drainage is shown in figure 62.

Field checking of the mapping done in the office showed that about 95 percent of the inter-

pretation was correct. Interpretations in open areas were accurate where contrasting tones were apparent. A partially wooded area of about 24 acres on the southeast side of the mapped area was judged in the office to be better drained than field examination indicated. Scattered small trees and light gray tone of the photograph on a 12-acre area were interpreted to mean well-drained soils. Field examination showed that this area had been cleared and was being cultivated.

Two areas of 1.3 acres each in the east and northeast parts were better drained than indicated by stereoscopic examination. The lack of contrast in tone did not give the soil scientist the correct clue.

A 0.8-acre area on the northeast was interpreted as part of a 10-acre poorly drained area. Field examination showed that it was poorly drained but was an area of high phase tidal

SCALE 1:15,840

ASCS—CDV-8F-113

Figure 61.—Plain photograph for comparison with figure 60.

marsh separated by a farm road from an adjoining area of tidal marsh.

The soils interpretation was based on two factors: (1) *Landform*—parallel bands of old beach ridges and sloughs. (2) *Tone*—white, whitish gray, and dark gray tones indicating good, imperfect, and poor natural soil drainage, respectively.

Landform.—The ridge-slough landform originated as parallel lines of beach dune sands modified by wind and water with time and shoreline recession. The landform in varying stages of development can be traced from the present shoreline beach sand dunes onto tree-covered steep-sided dunes and sloughs and across the broad ridge and slough areas for a distance of about 5 miles. The landform is more extensive and visible on the first (Pamlico) marine terrace than on the second (Talbot) terrace.

A difference in elevation of about 4 to 8 feet

between the ridges and sloughs shows on the photograph (fig. 60), but it cannot be readily seen under the stereoscope because the change is gradual. This difference in elevation makes the difference in the drainage class. All the area has A slope (0–2 percent) and class 1 erosion (none to slight). In the entire area of nearly level sand, the water table is high; in low areas it is at the surface where undrained; in higher areas at 4 to 6 feet below. The water table and drainage class affect the amount of vegetation cover that grows and accumulates in the surface soil.

Tone.—Ridge areas grow less vegetation and have less organic matter in the surface soil and therefore show up as white or chalky colored. Low areas having the most organic matter show up dark. Areas intermediate in elevation have an intermediate amount of organic matter and show up as grayish white. The chalky white-

Figure 62.—Relationship of major soils to land-scape and drainage in Pamlico Terrace, Coastal Plain of South Carolina. Numbers in parentheses give feet above sea level.

toned ridges are the Eustis soil series, intermediate areas are Seabrook and Kiawah series, and the dark-toned, low areas are the Rutlege series. The problem was to separate Seabrook from Kiawah. The clue was that Seabrook has more white than gray-white tone and that Kiawah has more gray-white than white. In wooded areas the higher well-drained to excessively well drained areas are in pine with about 75 percent crown cover plus some live oak and hickory. Gray areas show up indicating reflection of light from the ground. The pines show up dark. Poorly drained areas in woods are dark indicating a dense stand of pine, black gum, and low-growing shrubs. Intermediately drained areas are gray to dark gray indicating some ground reflection of light with a crown

cover between 75 to 100 percent of mostly pine and a few oaks.

On the second marine terrace the sand soils associated with the ridge-slough landform are the Lakeland, Ona, Plummer, St. Johns, and Rutlege series.

The time required to map the 640 acres follows:

- ½ hour in the office making photo interpretation
- 3½ hours in field checking the mapping done in the office
- ½ hour inking time
- 4½ hours—total time to map 640 acres (does not include travel time)

In both of these test areas the high proportion of agreement between photo interpretation and field examination resulted from several factors—the long experience that soil scientists had had in the areas, their intimate knowledge of the soils and of their relationships to landforms, the relatively simple patterns of the soils, and the noninterference of foliage in the interpretations of soils of forested areas. If any of these factors had been lacking, the photo interpretation might have been considerably less accurate.

Even with an intimate knowledge of the soils one would need to field check constantly and continually revise photographic guides because of the close relationships of soils and variations from photograph to photograph and place to place. Areas of such closely related soils as Kiawah and Seabrook are always suspect until examined in the field. Clues change from place to place and may not apply from one photograph to another even if appearances are the same.

Figure 63.—Section of a soil map compiled on a controlled mosaic base.

SOIL MAPS FOR PUBLISHED SOIL SURVEYS

Maps systematically compiled from soil-survey data delineated on aerial photographs make up the detailed soil map that is part of every published soil survey. Most of them cover a full county.

Usually the soil-survey data are superimposed on a controlled aerial mosaic base (fig. 63). This base produces uniformity of scale, provides a close match of images between adjoining map sheets, and makes possible the economical production of data on a base that is generally understood and useful.

The published map sheets are 11 x 17 inches in size and usually 1:20,000 in scale. Some are at scale of 1:31,680 or 1:15,840, depending on the complexity of soil delineations and on the intended use of the maps.

Some aerial photographs selected for the mosaic are from the same film used to print the photographs on which soil data were originally plotted. When a more recent aerial survey has been flown, it is used if the photographs have good quality and a satisfactory scale.

The SCS Cartographic Division may begin compiling the mosaic while the soil mapping is being completed in the field.

CONTROL FOR THE MOSAIC

A radial-control network is established for each project. This network provides a pattern of correctly located image points that are identified on the photographs. These provide a basis for rectifying and mounting the individual aerial photographs into a continuous map image.

First, a base grid is constructed at the scale selected for map compilation. The grid, usually constructed on the State rectangular coordinate system, forms a system of spaced lines of reference from which any ground position within the area may be plotted if the coordinates of that position are known. The positions of all geodetic control stations that can be identified and marked on the aerial photographs are then plotted on the base.

Because geodetic control stations are too widely spaced to provide a basis for rectifying and mounting aerial photographs, a system of radial-line triangulation is used to provide accurate locations for additional image points. Since for all practical purposes image displacements caused by relief are radial from the center of

the photograph, the true location of an object falls on a line drawn from the center of the photograph through the object. Therefore, the center point of the photograph is a triangulation station from which angles to various objects in the photograph area may be determined accurately.

To provide the triangulation pattern, nine image points are marked on each photograph: the center point, two "conjugate" center points that are transferred from adjacent photographs within the line of flight, two "wing" points on images in the sidelap areas opposite the center point, and four wing points that are transferred from adjacent photographs (fig. 64). Wing points are transferred to adjacent lines of flight much as the center points are transferred from photograph to photograph within a line of flight. Where images of geodetic control stations fall in the sidelap area, they may serve as wing points.

Figure 64.—Typical pattern of center and wing points circled on aerial photographs and corresponding slotted templates.

Where they do not, they are additional points that must be transferred to adjacent photographs within the line of flight. Contact prints are nearly always used to provide radial-line triangulation.

SCS uses the slotted-templet method of assembly to establish the radial-control net. A high-quality cardboard, such as three-ply railroad board or four-ply bristol board in sheets about the size of the aerial photographs, is used for the templets. A templet of the triangulation pattern of each photograph is made by punching a small hole in the center and by punching long, narrow radial slots that accurately reproduce the radial angles established on the photograph (fig. 64). Studs are "anchored" directly on the geodetic control stations plotted on the base, and the templet assembly is jointed by "floating" studs: one stud for each center hole and one for each intersection or radial lines through common wing points. The assembly is expanded or contracted until it fits the anchored studs. Then the locations of all the floating studs, fixed in position, are marked on the base (fig. 65). All radial-control positions are then transferred to 1/4-inch tempered hardboard sheets on which the mosaic will be compiled.

RECTIFIED PHOTOGRAPHS

On contact prints used to establish the radial-control network, a small dot of black ink is placed on the image points picked for the triangulation pattern; all other notations are removed from the prints. Then a copy negative of each contact print is made. A strip of thin, stable transparent plastic is placed over each flight line pictured on the hardboard control base, and a "strip" templet of each flight line is made by carefully circling on the plastic all control points common to the flight line. The copy negative, which has dotted image points that are displaced, is placed in a rectifying enlarging printer; the strip templet, which has corresponding points that are positioned correctly, is placed on the easel. The dotted points on the negative are projected, ratioed, and rectified until they fit the corresponding points on the strip templet. Then, the templet is removed; photographic paper is placed on the easel; and the rectified image of the copy negative is printed. Great care is taken to expose and develop photographs that will match the tone, contrast, and density of adjoining photographs.

MOSAIC ASSEMBLY AND REPRODUCTION

Because cut lines are less evident along features that have abrupt changes of tone, whenever possible match lines are selected where they can be made along prominent features such as roads, trails, streams, certain landforms, or boundaries of fields, forests, or bodies of water. Since only features that have about the same ground elevation may be precisely matched to adjoining photographs, in areas of moderate to severe relief, cut lines tend to follow a generalized contour line.

Some paper backing is removed along the cut and the remaining paper is sanded to provide a smoothly tapered joint with adjacent photographs. The segment is then positioned on the hardboard base, dotted points are matched to corresponding control points on the base, and photographic detail is matched to detail of adjacent photographs. The photographs are mounted with gum arabic adhesive (fig. 66).

When all photographs are mounted, a transparent dye solution is applied to darken any segment that has a photographic density lighter than that of adjoining photographs. Also, opaque paints in gray tones are applied to correct minor mismatches of prominent features. Finally, corners of individual map sheets are plotted on the mosaic, and each map sheet area is copied through a halftone screen on dimensionally stable film. The halftone negatives are used to print the mosaic images on bases for manuscript compilation and to make press plates for reproducing the photographic background of the map.

To prepare a base—called a greencote—for soil map compilation, dimensionally stable, clear plastic sheets are coated with a white pigment paint developed for scribing.

A green, water-soluble sensitizer is applied over this coating. The sheet is then exposed in contact with the halftone negative to produce a "manuscript base". The greencote reduces the passage of actinic light except through lines where the paint has been removed by scribing. The scribed greencote, therefore, serves as a negative for reproducing the manuscript.

MANUSCRIPT COMPILATION

The map manuscript is compiled by scribing on greencotes the main drainage, roads, soil

Figure 65.—Portion of a slotted-templet assembly. To mark the locations of studs on the base, a needle is passed through holes drilled through the studs.

Figure 66.—Mounting aerial photographs to form a controlled mosaic. Note the control points plotted on the hardboard base.

boundaries, soil symbols, and other data shown on field sheets. Main drainage and roads are first traced with a stylus (scribed) as they appear on the mosaic. The greencote is then placed under an overhead reflecting projector, which projects the field sheets to the greencote. The gray-tone image of the field sheet is enlarged or reduced to fit the green-tone image and the scribed drainage and roads on the greencote. The map compiler then scribes soil boundaries and other data that appear on the field sheet. Succeeding field sheets are thus projected until compilation on the greencote is completed.

After soil survey data are scribed on greencotes, identifying soil symbols are scribed in the soil areas (fig. 67). These symbols are taken from a working conversion legend prepared from the correlation and final soil legend. The scribed soil boundaries separating soils that are combined is opaqued out.

When the greencote manuscript is completed, the soil map is edited. Manuscript editors use the original field sheets and the correlation legend to check the accuracy of the soil-survey transfer, adjustment of soil boundaries to the mosaic image, and conversion of field soil symbols to the final map symbols.

COLOR-SEPARATION SCRIBING

Since on final map sheets soils data are printed in red and culture and drainage features in black these features must be separately scribed in negative (left-reading) form. To prepare a base for this scribing, the greencote manuscript is contact printed to a plastic "yellowcote." A yellowcote is similar to a greencote but is coated with yellow pigment paint and sensitized with blue watercote. Since all scribing on the greencote is positive (right-reading), the manuscript is contact-printed emulsion-to-emulsion on the yellowcote to reproduce a left-reading image. Two yellowcotes are printed from each manuscript. Only culture and drainage features to be printed in black are scribed on one yellowcote. Soil boundaries, erosion symbols, and other symbols to be printed in red, such as es-

carpments, depressions, and rock outcrops, are scribed on the other. Each scribed yellowcote is contact-printed on film to produce a right-reading film positive. Lettering to be printed on the final map sheet is added to these positives.

SCRIBING TOOLS

The scribing tools used are standard throughout the mapping industry. They are ground and adjusted to cut sharp lines of uniform weight and spacing. A tool designed to scribe highways is used to cut a double-line road that will have the specified width and line weight. A rigid scriber is used to scribe soil boundaries and perennial drainage, and a dotting instrument is used to make dots in the symbol that distinguishes intermittent drainage.

MAP LETTERING

To determine the proper position of place names and conventional signs, a lettering guide is first laid out on paper reproductions of the greencote. The size, style and weight of type, and the position of names and signs are shown on this guide. Soil symbols, names, conventional signs, and soil legends are printed on cellophane, the back of which is coated with wax to form a pressure-sensitive adhesive. Next, lettering is cut from the cellophane letterpress sheets and applied to the film positives reproduced from the yellowcotes. Names of roads, drainage, and cultural features are applied to the black plate positive; alphabetical soil symbols are added to the red plate positive after this positive has been placed over and registered with the first one. In this manner the two plates are properly registered, and overprinting of red and black features such as lettering or conventional signs is avoided.

FINAL EDIT

Each completed film positive is contact printed on film to produce a negative, and a composite color proof is made from these negatives. A final edit of the proof is made, and the negatives are corrected before press plates are made.

Figure 67.—Scribing soil symbols on greencote manuscript.

PHOTO INTERPRETATION IN WATERSHED-PROTECTION AND FLOOD PREVENTION PROGRAMS

Photo interpretation and related techniques, many of them similar to those used in making soil surveys, are also used to find facts about watersheds. Enough necessary information for watershed planning can be determined by photo interpretation to produce a significant saving in time and cost. A good knowledge of the physical and cultural features of the area being studied increases the accuracy as well as reduces the time required.

Photographs also form the basis for watershed measurements and are used to record information and to make mosaics and maps necessary for planning and working with local watershed sponsoring organizations.

Aerial photographs that have a slightly "flat" finish allow slight tone differences to be distinguished in lighter areas of photographs. These differences may be significant to the soil scientist or geologist. Though 1:20,000 is usually a good scale, the physical and cultural characteristics of the watershed could require a different scale. A 60-percent overlap within the flight line and 30-percent sidelap between flight lines give adequate stereoscopic coverage. The most recent aerial survey should be used; a single storm after a survey is flown could cause significant changes in stream channels and erosion conditions.

A folding pocket stereoscope of 2 $\times$ -power magnification is adequate for studying the pictures, but a stand stereoscope of 2 $\times$ - or 4 $\times$ -power is often preferred because the pictures can be moved more easily under it. A pricker or similar instrument is needed for pricking point locations. Also, for close study, a good quality reading-glass magnifier is essential.

Either colored pencils or inks may be used for delineating physical and cultural features. Ink may be better if the pictures will be used several years later or will receive rough field use.

A good color legend for delineation is: Drainage, blue; match lines, green; watershed lines, black; cultural features, red; erosion condition, orange.

All delineation should be made under the stereoscope and should be neat and accurate.

All features should be marked clearly.

To avoid duplication there should be a set of match lines on the photographs. Unless the terrain is unusually rough and steep, straight lines can be used for all four match lines.

The interpreter usually is given a county highway or topographic map on which a rough watershed boundary is drawn. But any general map of the county is adequate. The interpreter also has an index map of aerial photographs to be used. A "point of beginning" is set at the lowest level of the watershed before interpretative work is begun. This may be any point on a stream, but normally it is the point where the stream enters a larger stream or lake.

The interpreter locates this point on the photograph by noting on the map features that are near it and finding their images. Under the stereoscope he orients the stereoscopic pair showing the point of beginning and on both photographs pricks and circles this point with a pencil. Starting at the point, under the stereoscope he marks the ridge, or the dividing line from which the ground slopes toward the stream, between match lines on one of the photographs. The procedure is repeated on the succeeding stereoscopic pairs. The completed watershed boundary is a continuous line within which all land drains into one stream.

Next, stream or drainage lines within the watershed are drawn under the stereoscope. Generally stream channels appear as irregular striations and are easily seen. The interpreter overdraws these lines in blue. To keep photographs from becoming cluttered and to show only those drainage lines necessary for further study, the shortest length of stream to be overdrawn is specified before any lines are drawn.

Through stereoscopic study of aerial photographs, the photo interpreter can locate areas that contribute sediment to the stream. Sheet erosion, a major source of sediment, can be marked for field study. If gullies, which appear as irregular striated lines usually sloping toward a stream or drainageway, are in groups the entire area can be marked as a silt-contributing area. For single gullies the gully line is overdrawn.

Streambank erosion, which appears as jagged deep vertical cuts, is delineated by overdrawing the line or outlining the area of cutting. Other sediment-producing areas that must be marked are stream beds clogged with alluvial material; sand or silt bars in streams, which appear as elongated elliptical areas that have a slight mounding or raised surface; and alluvial fans at the mouths of streams or gullies, which appear as triangular areas with the peak or apex of the triangle pointed upstream.

To prepare flood-routing data, planners must know the configuration of the flood plain of a stream. The photo interpreter can assist the planner in this work by delineating the limits of flood plains in the watershed.

Some field work is necessary to locate the highest known water mark along a stream channel. Levels are run to these high-water marks and elevations are transferred by leveling to the opposite bank of the stream. This is repeated throughout each stream for which flood-routing data are required. Each point is marked on a photograph.

In the office the photo interpreter studies the photographs stereoscopically and, using the field-located points, delineates an approximate contour line. It is approximate—not a true contour—because the previous-high-water locations include the hydraulic gradient of the stream.

To help locate economical damsites, the photo interpreter studies the aerial photographs stereoscopically and selects sites where valley walls converge and the valley above is wide and flat. He marks these sites on a photograph for checking in the field. Often he marks the water line as well as the watershed line above each site.

He makes preliminary contour maps of the most desirable sites selected by the field check to determine the approximate storage capacity of each. Field crews may locate elevations along the center line of the proposed dam and upstream along the stream channel to a point higher than any elevation at the center line on the damsite. Points of elevation at intervals of about 10 feet are located on aerial photographs covering each damsite. The photo interpreter views the photographs stereoscopically and draws the approximate contour lines connecting these points. A preliminary estimate of reser-

voir storage capacity can then be computed by measuring the area of each applicable contour interval.

Land use patterns delineated to help planners estimate runoff should be marked on a separate set of aerial photographs to avoid congestion. If the photo interpreter is familiar with the area under study, he can easily identify almost all land uses. But he must be aware that climatic area affects the interpretations of land use. Land use patterns in arid areas are different from those in humid areas. Even within a climatic area, the tone of the photographic image varies depending on whether the ground surface is wet, moist, or dry.

BASE MAPS FOR WATERSHED PLANNING

All features delineated on aerial photographs are transferred to a base map, which for many areas is an uncontrolled mosaic. One advantage of a mosaic is the ease with which information from individual aerial photographs can be assembled and integrated for the whole watershed. The overall picture a mosaic provides is also often helpful when working with local people.

If a line map is used as the base map, the features on the photographs can be projected onto it with a vertical reflecting projector. A tracing may also be made from the photographs. Appropriate symbols and patterns identify the various features.

If a mosaic is used, it is compiled from a set of contact prints or from reduced-scale prints made by copying the watershed planning party's aerial photographs. Published maps are used to maintain overall scale and alignment. Prints are trimmed as necessary and then taped or pasted together to make the mosaic. Important names, physical and cultural features, and the watershed divide are usually added to the mosaic. Drainage may be delineated in white ink on the aerial photographs before they are copied for mosaicking.

In some areas for which a mosaic is compiled as a base map, a planimetric map of the watershed may also be prepared. Unless the mosaic was compiled from prints made after the drainage had been delineated on individual photographs, drainage is stereoscoped and then delineated on a manuscript overlay of acetate or

other plastic placed on the mosaic. Roads and other features taken from the photographs and information from U.S. Geological Survey quadrangles and county maps are also compiled on the manuscript overlay. Map features, including lettering, are cut on scribecoat placed in contact with the manuscript on a light table. A contact film positive made directly from the scribecoat yields diazo reproductions in the original scale. Other sizes can also be made.

TOPOGRAPHIC MAPS OF STRUCTURE SITES

Topographic maps of sites finally chosen for structures are prepared to make the preliminary design for the structure and a storage-data table. These can be made by stereoplotter or conventional survey methods.

For stereoplotting, aerial photographs are studied to select identifiable image points that are suitable for vertical control. They are analyzed stereoscopically to select suitable terminal points for taking measurements to scale the plotter models (areas covered by two overlapping photographs).

Setting up a stereoscopic model in the plotter requires a minimum of horizontal and vertical ground control. A base line, measured on the ground between two clearly identifiable points on the photographs, is required on about every third or fourth model to control horizontal scale. It should be long enough to measure 3 inches or more on the contact photograph and to fall entirely within the model. In addition, four vertical control points, one near each corner, are required for each model. They should have a middle tone on the photograph and be within a flat area about 15 or more feet in radius on the ground.

These control points must be positively identified in the field, positively identified and marked on the photographs, and easily seen in the stereoscopic model. Depending on the accuracy required, differential leveling or trigonometric leveling is used to determine the elevation of the four vertical control points.

The plotter operator should be a member of the field survey party. If this is not possible, the chief of the field survey party should become thoroughly familiar with the operation of the plotter and should know exactly what type of control points to select.

SCS uses Kelsh plotters to produce topographic maps that have fairly large scales and cover areas of 100 acres or more.

The Kelsh plotter provides a maximum of 5× enlargement and forms a single stereoscopic model. This model is produced by two precise projectors that project aerial pictures onto a tracing table. Each projector is provided with a contact glass positive made photographically from original aerial negatives. Each has a colored filter—one blue, the other red. The operator wears glasses with one blue and one red lens.

Once the stereoscopic model is alined with the control points, the operator sets what appears to be a floating dot of light on the elevation to be traced. This light comes through a pinhole in the center of the platen of the tracing table, which is a white disk about 3 inches in diameter. The operator keeps the dot on the ground as he moves the tracing table and an attached pencil traces the contour from below as shown in figure 68.

The Kelsh plotter is economical for preparing topographic maps. For example, from aerial

Figure 68.—Tracing contours with a Kelsh plotter.

photographs at a scale of 1:9,600, 4-foot contours can be plotted using a mapping scale of 1 inch=160 feet; at a scale of 1:4,800, 2-foot contours can be plotted using a mapping scale of 1 inch=80 feet.

Field time for obtaining the ground control points varies widely. When trigonometric leveling is used on the average site, it should be

possible to obtain the four ground control points and the measured distance for scale control in 1 day's time. In rough or brushy country, reconnaissance mapping can be plotted from control elevations obtained by barometric readings from precise altimeters. The accuracy of any topographic map can be no better than the field control on which it is based.

Principles and Concepts

- Overview
- Why digital soil mapping?
- Soil-landscape models
- Environmental covariates
- Training data
- Prediction of soil classes or properties
- Validation and uncertainty

Overview

Digital Soil Mapping

- The generation of geographically referenced soil databases based on quantitative relationships between spatially explicit environmental data and measurements made in the field and laboratory (McBratney et al., 2003)
- The spatial prediction of soil classes or properties from point data using a statistical algorithm

Overview

Digital Soil Map

- Raster composed of 2-dimensional cells (pixels) organized into a grid
- Each pixel has a specific geographic location and contains soil data

Overview

Conventional soil mapping

- “Where is the boundary between two soils?”
- Focus on the marginal areas

Digital soil mapping

- Central concept is well defined
- Variation expressed across the landscape

Why?

Digital soil mapping

- Illustrate spatial distribution of soil classes or properties
- Can document the uncertainty of the prediction
- Documentation of tacit knowledge
- Reproducible and consistent
- Can be used for
 - Initial soil maps
 - Update or refine existing soil maps
 - Generate specific interpretations
 - Assess risk
- Rapid inventory, re-inventory, and project-based management of lands in a changing environment
 - *FLEXIBLE*

Soil-Landscape Models

Factors of Soil Formation (Jenny 1941)

$$S = f (Cl, O, R, P, T)$$

- Soils are a function of 5 environmental factors
 - Climate
 - Organisms
 - Relief
 - Parent Material
 - Time
- Conceptual model (tacit knowledge)

Soil-Landscape Models

SCORPAN (McBratney et al., 2003)

$$S = f(S, C, O, R, P, A, N) + \varepsilon$$

- Soil, at a specific point in **space** and time
 - Soil classes, S_c
 - Soil attributes, S_a
- Empirical **quantitative** function of environmental covariates
 - Soil (class, or directly or remotely sensed property)
 - Climate
 - Organisms
 - Relief
 - Parent Material
 - Age
 - **N = Spatial Position**
- Plus an estimation of **error or uncertainty**

Soil-Landscape Models

SCORPAN facilitates

- *Quantification* of the relationships between environmental covariates and soil classes or properties in a *spatial context*
- *Estimation of error or uncertainty* of the spatial prediction of soil classes or properties

Environmental Covariates

Choosing covariates

- What factors influence soil formation?
 - **Link to pedological knowledge**
- What data do I have? Want? Need?
- Data should represent the multiple SCORPAN covariates that influence soil development in your project area

Multi-path smoothed wetness index

Relative Position

Environmental Covariates

$$S = f(S, C, O, R, P, A, N)$$

- Soil
 - Legacy soils data, field measurements
- Climate
 - Temp, precip, ET, solar radiation, etc.
- Organisms
 - Land cover, NDVI, spectral data and derivatives
- Relief
 - Elevation derivatives
- Parent material
 - Geology, spectral data and derivatives
- Age
 - Landform models
- Spatial position
 - Inherent in georeferenced data layers

Elevation and spectral data/derivatives

Environmental Covariates

Choosing covariates

- Consider resolution (spatial, spectral, temporal, radiometric) and what is required to meet the project needs
 - Target soil feature
- Compare needs to the range of data available
- **Elevation and spectral derivatives are a powerful combination for predicting soil classes or properties in most areas**
 - Project needs and physical features of the area may require only one of these data sources

Sampling for Training Data

Digital soil mapping is dependent upon the relationship between

- Predictor variables (covariates)
- Target soil feature (soil class or property)

True for all modeling methods

Samples of covariates representing the distribution of the target soil feature are required

- *Training data*
 - “Trains” the model to predict similar occurrences

Sampling for Training Data

Prediction is successful when

- Precise, observed locations of typical soil members are available

Directed (purposive) field samples

- Knowledge-based classification approaches
- Should not be used exclusively

Random or stratified sampling

- More robust
- Less prone to bias
- Sampling design appropriate for modeling objectives

Sampling for Training Data

DIGITAL SOIL MAPPING = FIELD WORK

Predict Soil Classes or Properties

Optimal set of SCORPAN covariates chosen

Training data collected

Apply a model to the data and predict soil classes or properties

Predicting Soil Classes

Classification is the process of predicting discrete classes

- Sorting pixels into finite number of classes based on data values and distribution in feature space
- If a pixel satisfies class criteria, then it's assigned to that class

Classification

Unsupervised

- Algorithm identifies clusters in the data
 - Non-informational clusters
- Analyst must interpret resulting clusters
 - Informational classes
- No training data required
- Exploratory
- K-means, ISODATA

Supervised

- Analyst selects training sites
- Algorithm creates decision boundaries from class statistics to cluster data
- Training data required
- Beyond exploratory
- Knowledge-based classification (ArcSIE), fuzzy classification, predictive modeling (random forests, neural networks)

Unsupervised Classification

ISODATA

- Shows natural clustering in the data and how potential classes may be distributed across the landscape
- Covariates include both terrain and spectral data derivatives

Boundary Water Canoe Area Wilderness, MN

Supervised Classification

Predictive modeling (machine learning)

- Classes and probability surface for one class from random forests (tree-based)
- Covariates include both terrain and spectral derivatives

Boundary Water Canoe Area Wilderness, MN

Predicting Soil Properties

Regression and interpolation methods
predict continuous soil properties

Regression

- Estimates the relationship between the dependent (soil observations) and independent variables (covariates)
- Linear regression, logistic regression, random forests

Interpolation

- Models spatial patterns based on values at known locations and the assumption that locations that are closer to one another are more similar than those that are further apart
- Geostatistics (kriging)

Regression

Predictive modeling (machine learning)

- Properties and associated probability surface from generalized linear model (regression)

Beef Basin area, UT

Predicting Soil Properties

Raster stack

- Continuous raster soil properties
- Key soil property layers at fixed depths
 - 0-5cm, 5-15cm, 15-30cm, 30-60cm, 60-100cm and 100-200cm
 - Target soil properties
 - Total profile depth (cm)
 - Plant exploitable soil depth (cm)
 - Organic carbon (g/kg)
 - pH (x10)
 - Sand (g/kg)
 - Silt (g/kg)
 - Clay (g/kg)
 - Gravel ($\text{m}^3 \text{m}^{-3}$)
 - ECEC (cmolc/kg)
 - Bulk density of fine earth (<2mm) fraction (excluding gravel) (Mg/m^3)
 - Bulk density of whole soil (includes gravel) (Mg/m^3)
 - Available water holding capacity (mm)
- Prediction uncertainty

Concept
soil property

Predicting Soil Properties

Continuous soil property raster stack

- Interpretations for management and use
 - The data stack becomes the database
 - Add slope, climate, etc. layers needed for calculating interpretations
- Class data – taxonomic or technical

Interpolation

Geostatistics

- Ordinary kriging applied to predict soil K concentrations

Salt Lake Valley, UT

Validation and Uncertainty

All soil mapping methods rely on models

- Conventional soil mapping
 - Qualitative
 - Relies on conceptual model (CLOPPT)
- Digital soil mapping
 - Quantitative
 - Relies on quantitative model (SCORPAN)

All models approximate reality and are subject to error and uncertainty

Validation and Uncertainty

Quantitative nature of digital soil mapping

- Lends itself to quantitative assessments of accuracy and uncertainty

Communication of accuracy and uncertainty associated with soil spatial predictions is imperative

Integral part of delivering modeled products given their use in resource management decision making and risk assessment

Accuracy

Predicted values on a map will deviate from true values to some extent

Accuracy

- Difference between predicted value at a location and measured value at same location
- High prediction accuracy
 - Small difference between predicted and observed values

Accuracy measures quantify prediction quality using a validation data set

Accuracy

Soil classes

- User's, producer's, overall accuracy
 - Confusion matrix
- Kappa, Tau index (weighted Tau), Brier score

Soil properties

- MSE, RMSE, standard error, modified R^2

Uncertainty

Sources

- Positional accuracy of pedon location
- Covariate accuracy (e.g., vertical uncertainty of DEM)
- Soil class or property measurement (e.g., taxonomic classification or lab measurement)
- Model structure (e.g., using linear model for curvilinear data)

Uncertainty

Soil classes

- Memberships or probabilities
- Class confusion measures (confusion index, distance files, entropy)

Soil properties

- Prediction intervals

Uncertainty measures can be generated during the modeling process or calculated from results, and represented spatially

Uncertainty

Soil classes – confusion index

*Powder River Basin, WY
Brungard et al., 2015*

Digital Soil Mapping: Stages and Processes

Digital Soil Mapping

Summary

- Predicting soil classes or properties from field observations and environmental covariates using a statistical algorithm
- Spatial representation of classes or properties
- Includes estimates of accuracy and uncertainty
- Consistency and reproducibility
- Flexible product to meet variety of user needs

Digital Soil Mapping

Focus

- Fundamental pedology
 - **Knowledge** of the soil resource as a natural body
 - Existing and newly acquired
 - **Field component**
- Latest technological resources
 - Applied adaptively throughout process and in **combination** with soil knowledge

Digital Soil Mapping Training

Foundational Prerequisites Taken in the Following Order:

1. Spatial Analyst Workshop (NRCS-NEDC-000271)
2. Statistics for Soil Survey Part 1 (NRCS-NEDC-000400)
3. Intro to Digital Soil Mapping (NRCS-NEDC-000272)

Digital Soil Mapping with ArcSIE (NRCS-NEDC-000273)

- Prerequisites
 - All 3 foundational prerequisites

Statistics For Soil Survey Part 2 (NRCS-NEDC-000332)

- Prerequisites
 - Statistics for Soil Survey Part 1

Remote Sensing for Soil Survey Applications (NRCS-NEDC-000244)

- Prerequisites
 - All 3 foundational prerequisites
- Intro to Digital Remote Sensing (available on-line from Michigan State University)

FORESTER'S GUIDE TO AERIAL PHOTO INTERPRETATION

This handbook was written as a practical reference on techniques of aerial photo interpretation in forest inventory. It is for the forester with a casual knowledge of the subject. While oblique photographs are occasionally useful for interpretation, this manual emphasizes stereoscopic interpretation of vertical aerial photographs available from various agencies of the U.S. Department of Agriculture (USDA). Figure 1 (foldout, inside back cover) is an example of a vertical aerial photograph.

With training, the forester can use aerial photographs to locate property boundaries and trails, determine bearings and distances, identify classes

of vegetation, and measure areas. Experience will enable him to improve the efficiency of forest inventories by distributing field samples on the basis of photo stratifications. In some instances, he may even be able to estimate timber volumes directly from the photographs.

While photo interpretation may make the forester's job easier, there are limitations. Accurate measurements of such items as tree diameter, form class, and stem defect are possible only on the ground. Aerial photographs are best used to complement, assist, or reduce field work rather than take its place.

TYPES OF AERIAL PHOTOGRAPHS

Oblique photographs are taken with the axis of the aerial camera at various angles between the horizon and the ground. *High* obliques show the horizon on the photograph; *low* obliques do not. An oblique photograph covers a larger area compared with a vertical photograph from the same altitude, but its usefulness is limited to fairly level terrain where the view is not obstructed by ridges. For this reason, and because obliques do not readily lend themselves to stereoscopic viewing, they are seldom used by foresters in the United States.

Vertical photographs are taken with the aerial camera pointed straight down at the ground, or as nearly so as feasible. Overlapping exposures in each flight line permit an interpreter to study vertical photographs three dimensionally with a stereoscope. Because such prints have become so useful for mapping and interpretation, the term "aerial photo" is normally assumed to denote a vertical photograph and will be thus applied in this handbook.

Mosaics are composite pictures assembled from as many individual, vertical photographs as may be required to cover a specified area; they are usually constructed to provide a pictorial representation and a planimetric approximation of a fairly extensive ground area. The principal kinds of mosaics, in order of ascending scale reliability are: (1) index or uncontrolled mosaics, (2) semi-

controlled mosaics, (3) controlled mosaics, and (4) orthophotomosaics.

The *index mosaic* is simply an assembly of untrimmed contact prints that are pasted up in overlap and sidelap positions so that image detail is matched and the original flight-line position of each exposure is reconstructed. The entire layup is usually rephotographed at a smaller scale for use as a pictorial reference to individual prints. An *uncontrolled mosaic* is assembled in a similar fashion (i.e., without ground control) except that each frame is first trimmed down to its "effective" or non-overlapping area. Then, each trimmed portion is matched together like the segments of a jigsaw puzzle.

A *semi-controlled mosaic* differs from the uncontrolled type in that it is assembled with the aid of limited ground control points. It is thus intermediate in scale reliability, depending somewhat on the local relief of the area depicted.

A *controlled mosaic* is one that is directly tied to an extensive network of ground control points, and it is usually assembled from prints that are both rectified and ratioed. As a result, the mosaic will approximate planimetric map accuracy in regions of flat to gently rolling terrain. However, distortions due to relief are *not* eliminated in controlled mosaics, and *some* images will be displaced from their true plan positions.

OBTAINING AERIAL PHOTOGRAPHY

An *orthophotograph* is a reproduction, prepared from ordinary perspective photographs, in which image displacements caused by tilt and relief have been entirely removed. When these unique photographs are assembled into an *orthophotomosaic*, the result is a picture-map with both scale and planimetric detail of high reliability. When such mosaics are overprinted onto standard mapping quadrangles, they are referred to as orthophotoquads.

Users of this guide will ordinarily rely on prints of existent photography flown for public agencies. Thus there is no need here to discuss specifications for new aerial photography. Details of flight planning and photographic contracts are covered in the *Manual of Photogrammetry* and the *Manual of Photographic Interpretation* (1, 2).¹

Sources of cartographic information.—The National Cartographic Information Center (NCIC), established in 1974 by the U.S. Geological Survey, Department of Interior, provides a national information service to make cartographic data of the United States more easily accessible to the public and to various Federal, State, and local agencies. At present, more than 30 Federal agencies collect and prepare cartographic data. Existing data includes more than 1.5 million maps and charts, 25 million aerial and space photographs, and 1.5 million geodetic control points.

Much of this information is available by contacting NCIC at the following address:

**National Cartographic Information Center
U.S. Geological Survey
507 National Center Rm. 1C101
Reston, VA 22092**

NCIC does not obtain cartographic data from present holders; rather it collects and organizes descriptive information about the data, such as location, availability, and ordering instructions. Existing government and private data centers will continue to hold and distribute cartographic data, and some will provide local users with direct access to NCIC information through their existing public service facilities.

Sources of aerial photography.—A large proportion of the existing aerial photography of interest to foresters is held by Federal agencies within the Department of Agriculture. Principal among these are the Agricultural Stabilization and Conservation Service (ASCS), the Forest Service (FS) and the Soil Conservation Service (SCS).

The ASCS has the responsibility of contracting for aerial photography for all three agencies. It

also has the responsibility for providing reproductions from all ASCS and FS photography and from SCS photography that is 2 or more years old. A central laboratory for ordering this photography is provided by ASCS:

**Aerial Photography Field Office
ASCS/USDA
P. O. Box 30010
Salt Lake City, Utah 84125**

Films, season, and date of photography.—Two types of black-and-white aerial film are in common use: panchromatic and infrared. Infrared is usually modified by a minus-blue filter to reduce contrast and improve image resolution. Panchromatic photography offers better resolution and lighter shadows but exhibits little tonal contrast among forest types. Modified infrared photography presents a maximum of contrast between conifers and deciduous hardwoods, but wet sites and shadows register in black, thus restricting interpretation.

In Western United States, where coniferous trees predominate, panchromatic film is more likely to be used. Conversely, foresters managing eastern hardwoods often prefer infrared photography because forest type separation is more definite. In figure 2, dark-toned pines (A) are readily differentiated from the light-colored upland hardwoods (B) on the infrared stereogram, but there is little tonal contrast on the panchromatic exposures. Also the farm pond at (C) is obvious on the infrared prints, but may be completely overlooked on the panchromatic photographs.

If measurements are needed for deciduous species, both kinds of photography should be taken during the growing season. Infrared is likely to be used specifically for forestry purposes and usually meets this requirement. On panchromatic photographs taken in winter, conifers can be distinguished from hardwoods, but interpretation of hardwood stand-sizes is difficult.

If there is a choice between photography of different dates, you should select the most recent. Also, if there is more than one source, you should choose which photograph shows the most information or use the photographs in conjunction. In regions characterized by rapid tree growth and frequent cuttings, the value of photos more than 5 years old is questionable.

With minor exceptions, ASCS and SCS photography is taken with black-and-white panchromatic film. A large percentage of the more recent FS photography is taken on color film, with most of the remainder taken on color infrared, black-and-white infrared, or panchromatic.

Photo scales and enlargements.—In earlier years, the negative scale of ASCS and SCS photography was commonly set at 1:20,000 (1,667

¹ Italic numbers in parentheses refer to Literature Cited, page 40.

feet per inch), while much of FS photography was set at a scale 1:15,840 (1,320 feet per inch). The FS has established a standard scale program of 1:24,000 for resource photography and 1:80,000 for high altitude photography.

Since about 1972, the negative scale of most ASCS photography has been set at 1:40,000 (3,333 feet per inch). Much of the FS photography acquired prior to the adoption of a standard scale was at a scale of 1:15,840 (1,320 feet per inch). Resource photography now used is at a scale of 1:24,000 (2,000 feet per inch). Scales of SCS photography are mostly in the range of 1:38,000 (3,167 feet per inch) or 1:58,000 (4,333 feet per inch).

The standard 9- by 9-inch contact prints can be enlarged, of course. Enlargements up to 38 by 38 inches are available, with commensurate increases in scale and image size. For example, a common product used by ASCS is an enlargement rectified to a scale of 1:7,920 (660 feet per inch) on sheets that measure 24 by 24 inches.

Unless sophisticated equipment is available, it is difficult to study enlargements stereoscopically. Therefore, contact prints are recommended for general use by foresters who must rely on simple pocket stereoscopes.

Paper surface, weight, and contrast.—Black-and-white prints ordered from ASCS are made on a medium-weight, semi-mat, resin-coated base material; as a result, the prints are both stable and water-resistant. Reproductions are also available in the form of positive film transparencies; as a rule, these provide greater sharpness and clarity of detail than ordinary prints.

When a specific degree of contrast is required, this should be indicated when ordering. If possible, the order should be accompanied by a sample print that illustrates the desired amount of density and contrast.

Coverage available.—USDA aerial photography covers more than 80 percent of the United States, including portions of Alaska and Hawaii. Coverage is updated periodically according to pro-

gram needs; this results in new photography every 5 to 10 years for many areas.

The ASCS annually publishes "status maps" which are available free upon request. These maps show the most recent coverage available for a given area, the scale of photography, focal length of the camera lens, and number of photo index sheets required to cover a project area.

Ordering photography from ASCS.—Photo index sheets or index mosaics, showing the relative positions of all individual photographs within a given county (fig. 3a), can be examined at local offices of the Agricultural Stabilization and Conservation Service or the Soil Conservation Service. The number of index sheets per county varies from one to six or more. It is possible to visit an ASCS office, select desired photos from an index, and order them on the spot.

Forest Service indexes are usually available for inspection in local supervisor's offices or on ranger districts. Instead of conventional photographic indexes, the Forest Service now uses "spot indexes," i.e., maps showing the locations of photo centers (fig. 3b).

If you are interested in aerial photography of a distant county, you may wish to purchase an index of that county and make your selection. Again, your own county ASCS office will help you order the index and will provide assistance in selecting the photos that will best suit your needs. Prints are identified by a county symbol (or by a special state and county code), and by film roll and exposure number (fig. 1). Other items to specify are date of photography, scale, and type of reproduction (print size, weight, finish, contrast, etc.).

Special order blanks and current price lists may be obtained through local ASCS offices. Orders must be accompanied by advance payment, and 3 to 4 weeks should be allowed for delivery.

If you do not have access to the appropriate index sheet, an alternative is to outline the area of interest on a reliable map. This map can then be sent to the Aerial Photography Field Office in Salt Lake City with your inquiry.

Figure 2.—Modified infrared (above) and panchromatic photography made in the North Carolina Piedmont during June. Exposures were made simultaneously with a dual aerial camera system. Scale is 1,320 feet per inch. Prints may be viewed three-dimensionally with a lens stereoscope.

Figure 3b.—The "spot index" showing plotted positions of flight lines and photo centers, used by the Forest Service.

PREPARING PHOTOGRAPHS FOR STEREO-VIEWING

Equipment Needed

Equipment considered essential by one interpreter may be of limited use to another; nevertheless, the forester who anticipates a continued use of aerial photographs will probably find the following list closely approximates his minimum needs.

Lens stereoscope, folding pocket type.
Parallax bar or parallax wedge for measuring object heights.

Engineer's scale, graduated to 0.02 inch.
Tree crown-density scale.
Tree crown-diameter scale.
Dot grids for acreage determination.
China-marking pencils for writing on photographs.
Carbon tetrachloride and cotton for cleaning photographs.
Drafting instruments, triangles, and drafting tape.
Needles for point-pricking.
Tracing table.
Magnetic or spring-clipboard for holding stereo-pairs.
Proportional dividers.

If purchased with discretion, the items can be obtained for less than \$250. For a price list of photo interpretation aids available from the Forest Service, write to the Engineering Staff, Forest Service, U.S. Department of Agriculture, P.O. Box 2417, Washington, D.C. 20013.

Many foresters will already own drafting instruments, dot grids, and pocket stereoscopes. A satisfactory tracing table can be improvised by installing a uniform light source under a glass surface. Fluorescent tubes are better than incandescent bulbs because they produce less heat. A sheet of frosted cellulose acetate between two pieces of ordinary single-weight glass serves well when special frosted glass is not available.

If the forester uses aerial photographs regularly and becomes adept in interpretation and mapping, he may wish to acquire more expensive equipment, such as a mirror stereoscope, vertical sketchmaster, reflecting projector, or radial plotting devices. The *Manual of Photogrammetry* (1) contains information on such equipment.

Preparing the Photographs

Photographic flights are planned so that prints will overlap about 60 percent in the line of flight and about 30 percent between flight strips. For effective stereo-viewing, prints must be trimmed to the nominal 9- by 9-inch size, preserving the four fiducial marks at the midpoint of each of the edges (fig. 1). Then:

1. *Locate the principal point (PP) or center of each photograph.* Aline opposite sets of fiducial marks with a straightedge or triangle. Draw a cross at the center with a wedge-pointed pencil, and make a fine needle hole at the intersection.
2. *Locate the conjugate principal points (CPP's) on each photograph*—the points that correspond to PP's of adjacent photographs. Adjust the stereoscope until distance between centers of lenses corresponds with interpupillary distance (usually about 2.5 inches). Arrange the first two photographs of a given flight line so that corresponding gross features overlap. Shadows should be toward the observer; if they fall away from the viewer there is a tendency to see relief in reverse. Clip down one photograph. Move adjacent photograph in direction of line of flight until corresponding images on each print are about 2.2 inches apart. Place lens stereoscope over prints *parallel to line of flight* so that the left-hand lens is over the left photograph and the right-hand lens is over the same image on the right photograph. The area around the PP will be seen as a three-dimensional image. The movable photograph should then be fastened down. While viewing this area through the stereoscope, place a needle in the same area on the adjacent photograph until it appears to fall precisely in the hole pricked for the PP. This locates the CPP (fig. 1), though a monocular check should

be made before the point is permanently marked. Repeat for all photographs; each will then have one PP and two CPP's except that prints falling at the ends of the flight lines will have only one CPP. Ink a 0.2-inch diameter circle around each PP and CPP (fig. 1).

3. *Locate the flight lines on each print by alining the PP's and CPP's.* Connect the edges of the alined circles with a fine ink line (fig. 1). Because of lateral shifting of the photographic plane in flight, a straight line will rarely pass through the PP and both CPP's on a given print.
4. *Determine the photo base length for each stereo-overlap* by averaging the distance between the PP and CPP on one print and the corresponding distance on the overlapping print. Measure to the nearest 0.02 inch and record on the back of each overlap. There will be two average base lengths for each print, i.e., one for each set of overlapping flight lines.

Alining prints for stereoscopic study.—A print is selected and clipped down with shadows toward the viewer. The adjacent print is placed with its CPP 2.2 inches from the corresponding PP on the first print. With flight lines superimposed, the second print is positioned and clipped down. The stereoscope is placed with its long axis parallel to the flight line and with the lenses over corresponding images. In this way an overlapping strip 2.2 inches wide and 9 inches long can be viewed by moving the stereoscope up and down the overlap area (fig. 4).

A. PRELIMINARY PHOTO ORIENTATION

B. FINAL PHOTO ALIGNMENT

Figure 4.—Method of alining 9- by 9-inch contact prints for viewing with a lens stereoscope. Compare this diagram with figure 1.

While the photos are still clipped down, the prints can be flipped into reverse position with the opposite photo on top. This presents another area of the overlap for stereo-viewing. To study the

narrow strip between, the edge of one print must be curled upward or downward and the stereoscope moved parallel to the flight line until the "hidden area" comes into view (fig. 5).

Figure 5.—Slotted clip board for viewing the "hidden area" of overlapping contact prints with a lens stereoscope. The area indicated by arrows cannot be stereoscopically studied when prints are lapped as in figures 1 and 4.

PHOTO SCALE, BEARINGS, AND DISTANCES

The vertical aerial photograph presents a true record of angles, but measures of horizontal distances vary widely with changes in ground elevations and flight altitudes. The nominal scale (as 1:20,000) is representative only of the datum, an imaginary plane passing through a specified ground elevation above sea level. Calculation of the average photo scale will increase the accuracy of subsequent photo measurements.

Aerial cameras in common use have focal lengths of 6, 8.25, or 12 inches (0.5, 0.6875, or 1.0 ft.). This information, with the altitude of the aircraft above ground datum, makes it possible to determine the representative fraction (*RF*) or natural scale:

$$RF = \frac{\text{Focal length (ft.)}}{\text{Flying height above ground (ft.)}}$$

The height of the aircraft is rarely known to the interpreter, however, and photo scale is more often calculated by this proportion:

$$RF = \frac{\left[\begin{array}{l} \text{Photographic distance} \\ \text{between two points (ft.)} \end{array} \right]}{\left[\begin{array}{l} \text{Ground or map distance} \\ \text{between same points (ft.)} \end{array} \right]}$$

Determining scale from ground measurements.—Select two points on opposite sides of the print so that a line connecting them passes near the PP. If the points are approximately equidistant from the PP, the effect of photographic tilt will be minimized. (Tilt results when the camera axis deviates from the vertical at the instant of exposure. It is often present, but generally not enough to be readily noticed.) Points must be easily identifiable on the ground so that the distance between them can be precisely measured. Gas and power line rights-of-way, highways, and railroads offer clearings where ground distances can be quickly chained. It is not necessary to calculate the scale of every photograph in a flight

strip. In hilly terrain, every third or fifth print may be used; in flat topography, every tenth or twentieth. Scales of intervening photographs can be obtained by interpolation.

Office checks of photo scale.—Scale determination from ground measurements is laborious and expensive; hence other methods should be used wherever possible. If a U.S. Geological Survey quadrangle sheet is available, the map distance can be measured and used in the formula, provided the same distance can be identified for photo measurement (fig. 6).

Another alternative is presented in areas of flat terrain where General Land Office subdivisions of sections, quarter-sections, and forties are visible on the photographs. Since the lengths of these

subdivisions will be known, they can also be used as ground distances. A given section may rarely be exactly 5,280 feet on a side, but determining scale by this method is more accurate than accepting the nominal scale.

Compass bearings and distances.—Although flight lines usually run north-south or east-west, few photographs are oriented exactly with the cardinal directions. For this reason, a reference line must be located before bearings can be determined. The method described is used by field teams on the U.S. Forest Survey:

1. Select a straight-line feature such as a highway, section line, or field edge and determine its bearing. Draw this reference line on the photograph, extend it as necessary, and record the bearing (fig. 7).

Figure 6.—Determination of photo scale from a U.S. Geological Survey map. Map scale is 1:24,000 or 2,000 feet per inch. Map distance between X and Y is 2.00 inches, or 4,000 feet on the ground. Photo distance is 4.80 inches. Thus the photo scale is $4.80 \div 4,000 \times 12$, or 1:10,000. (Courtesy of Abrams Aerial Survey Corporation.)

2. Pick a point of beginning (PB) from which the line of approach to a field location will be run. This should be some feature visible on both photograph and ground, such as a fence corner, barn, road intersection, or stream fork. Draw a line on the photograph from the PB to the location, and extend until it intersects the reference line. Measure the angle between the two lines with a protractor and determine the bearing of the line of approach.
3. Measure the distance between the PB and the field location to the nearest 0.01 inch and convert to feet or chains at the calculated photo scale. At a scale of 1:20,000, a measure of 0.01 inch equals 16.67 feet or about 25 links. In figure 7, the distance from PB to the center of the circular field plot is 1.15 inches, or about 29 chains. Common scale conversions are given in table 1.

TABLE 1.—Scale conversions for vertical aerial photographs ¹

Representative fraction (scale)	Feet per inch	Chains per inch	Inches per mile	Acres per square inch	Square miles per square inch
(1)	(2)	(3)	(4)	(5)	(6)
1:7,920	660.00	10.00	8.00	10.00	0.0156

1:24,000	2,000.00	30.30	2.64	91.83	.1435
1:25,000	2,083.33	31.57	2.53	99.64	.1557
1:31,680	2,640.00	40.00	2.00	160.00	.2500
Method of calculation	RFD 12	RFD 792	63,360 RFD	(RFD) ² 6,272,640	Acres/sq. in. 640

¹ Conversions for scales not shown can be made from the relationships listed at the bottom of each column. With the scale of 1:7,920 as an example (column 1, line 1), the number of feet per inch is computed by dividing the representative fraction denominator (RFD) by 12 (number of inches per foot). Thus, $7,920 \div 12 = 660$ feet per inch (column 2). By dividing the RFD by 792 (inches per chain), the number of chains per inch is derived (column 3). Other calculations can be made similarly. Under column 4, the figure 63,360 represents the number of inches in one mile; in column 5, the figure 6,272,640 is the number of square inches in one acre; and in column 6, the number 640 is acres per square mile.

IDENTIFYING FOREST TYPES AND TREE SPECIES

Forest types and tree species can often be delineated with greater accuracy and lower cost on aerial photographs than by ground methods. The degree to which species groups can be recognized depends on the quality, scale, and season of photography; the type of film used; and the interpreter's training. A general knowledge of forest associations and plant ecology is helpful, but field

experience in the specific area to be mapped is far more valuable.

A generalized map of forest regions in the United States is shown in figure 8. The tree species listed provide the first step in identification, i.e., the elimination of those cover types not likely to occur in a given locality. The second step, heavily dependent on a knowledge of local

Figure 7.—Determination of compass bearing and distance to a field plot on a USDA contact print. Scale is 1,667 feet per inch.

vegetation, is to establish which forest types may be encountered in the area to be mapped.

Recognition of an individual species, often feasible only on large-scale photography, is normally the culmination of intensive study. Obviously the forest interpreter must be familiar with branching patterns and crown shapes of all important species in his region. Mature conifers in sparsely stocked stands can often be recognized on 1:20,000 USDA photography by the configuration of their crown shadows falling on level ground (fig. 9). Studying oblique photographs of trees has been helpful to many foresters.

Recognition of species on vertical photographs also requires a familiarity with tree crowns as seen in overhead views (fig. 10). While overhead crown characteristics are not always apparent on 1:12,000 to 1:20,000 photographs, they can be highly useful on large-scale stereograms. Photo scales as large as 50 feet per inch have been utilized for tree species identifications in Canada (16, 20).

Aside from shadows, crown shapes, and branching patterns, the features to consider in identifying tree species are photographic texture (smoothness or coarseness of images), tonal contrast, relative sizes of tree images at a given photo scale, and topographic location or site. Most of these are rather weak clues when observed singly, yet together they may be the final link in identification by elimination.

For some parts of the United States and Canada,

vegetation keys are available aids in tree species recognition. Keys are useful for training new interpreters and for reference by more experienced personnel. Depending on the method of presenting diagnostic features, photo interpretation keys may be grouped into two general classes: *selective* keys and *elimination* keys. Selective keys are usually illustrations and descriptions of trees in a specific region, e.g., pines of Florida. They are organized for comparative use; the interpreter merely selects the key example that most nearly coincides with the forest stand he must identify. By contrast, elimination keys require the user to follow a step-by-step procedure, working from the general to the specific. One of the more common forms of elimination keys is the dichotomous type. Here the interpreter must continually select one of two contrasting alternatives until he progressively eliminates all but the item being sought.

A sample elimination key for identifying northern conifers is reproduced here. It may be used to identify tree species pictured in the large-scale stereograms in figure 11. In original form, this Canadian key had additional descriptive materials and illustrations such as those shown in figures 9 and 10 (16).

Vegetation keys are most easily constructed for northern and western forests where conifers predominate, because there are relatively few species to be considered and crown patterns are rather distinctive for each important group. By con-

trast, few if any, reliable keys are available for the highly variable hardwood forests of Southern and Eastern United States.

While the scope of this handbook does not permit a detailed treatment of all important forest types throughout the United States and Canada, examples are given in figures 12 through 18.

Key to the Northern Conifers ²

1. Crowns small, or if large then definitely cone-shaped.
2. Crown broadly conical, usually rounded tip, branches not prominent ----- cedar
2. Crowns have a pointed top, or coarse branching, or both.
 - crowns narrow, often cylindrical, trees frequently grow in swamps ----- swamp type
 - crowns conical, deciduous, very light-toned in fall, usually associated with black spruce ----- black spruce
 - crowns narrowly conical, very symmetrical, top ----- tamarack

- pointed, branches less prominent than in white spruce ----- balsam fir
- crowns narrowly conical, top often appears obtuse on photograph (except northern white spruce), branches more prominent than in balsam fir ----- white spruce, black spruce (except swamp type)
- crowns irregular, with pointed top, has thinner foliage and smoother texture than spruce and balsam fir ----- jack pine
- 1. Crowns large and spreading, not narrowly conical, top often not well defined.
- 3. Crowns very dense, irregular or broadly conical.
 - 4. Individual branches very prominent, crown usually irregular ----- white pine
 - 4. Individual branches rarely very prominent, crown usually conical ----- eastern hemlock
- 3. Crowns open, oval (circular in plain view) ----- red pine

MAPPING FROM AERIAL PHOTOGRAPHS

Type maps are no longer considered essential by all foresters, but at times their cost may be justified. A general ownership map showing principal roads, streams, forest types, and condition classes may be desired for management planning and illustrative purposes. Also, in making a photo-controlled ground cruise where precise forest-area estimates are required, it may be necessary to measure stand areas on controlled maps of known scale rather than directly on contact prints. This is particularly important where topography causes wide variation in photo scales.

The wise interpreter will delineate only those types that he can consistently recognize. For maximum accuracy, type lines should be drawn under the stereoscope. As lines made with a china-marking pencil are easily removed with carbon tetrachloride or benzene, this method is recommended for preliminary work. Water-soluble ink is also suitable. Permanent markings can be made with drawing ink after types have been verified by ground reconnaissance.

Uncontrolled maps.—Where area measurement is not critical, simple uncontrolled type maps can be prepared at photo scale by direct tracing. Tract boundaries are drawn within the "effective area"³

² Reproduced by permission of L. Sayn-Wittgenstein, Forest Research Branch, Canada Department of Forestry (16).

³ If 9- by 9-inch photographs with 60-percent endlap and 30-percent sidelap are assumed, alternate photographs will have effective areas of about 7.2 by 6.3 inches.

of alternate prints in each flight strip. Photographs are interpreted under the stereoscope, and all types and planimetric data are outlined. The detail is then traced onto frosted acetate or vellum, from one annotated print at a time. If boundaries are accurately drawn on interpreted prints to include all of the tract without duplication, the traced data from adjoining prints should match up without difficulty. To assure standardization in type recognition, it is desirable to have one man perform all interpretation work.

Uncontrolled maps are no more accurate for area measurement than the photographs from which they were prepared, but they may suffice for management plans and illustrations. Where flat terrain predominates, average photo scales vary only slightly and tracings may approach the accuracy of controlled maps.

Controlled maps.—Base maps of uniform scale may be required for photo-controlled ground cruises, as precise measures of forest area by type and stand size are essential for accurate volume estimates. In flat terrain, average photo scale can be determined and acreages measured directly on contact prints, but in steep topography variations in photo scale require the transfer of forest types to base maps for accurate area measurement. The most common way of adjusting variable photo scales to controlled maps is by constructing "radial line plots" or by preparing plat sheets from field notes of the General Land Office. As construction of a radial line plot is complex and has been ade-

PRINCIPAL TREES OF THE FOREST REGIONS

NOTE.—The order indicates the relative importance or abundance of the trees

ROCKY MOUNTAIN FOREST

Northern Portion (Northern Idaho and Western Montana):

Lodgepole pine
Douglas-fir
Western larch
Engelmann spruce
Ponderosa pine
Western white pine
Western redcedar
Grand and alpine firs
Western and mountain hemlocks
Whitebark pine
Balsam poplar

Eastern Oregon, Central Idaho, and Eastern Washington:

Ponderosa pine
Douglas-fir
Lodgepole pine
Western larch
Engelmann spruce
Western redcedar
Western hemlock
White, grand, and alpine firs
Western white pine
Oaks and junipers (in Oregon)

Central Montana, Wyoming, and South Dakota:

Lodgepole pine
Douglas-fir
Ponderosa pine
Engelmann spruce
Alpine fir
Limbber pine
Aspen and cottonwoods
Rocky Mountain juniper
White spruce

Central Portion (Colorado, Utah, and Nevada):

Lodgepole pine
Engelmann and blue spruces
Alpine and white firs
Douglas-fir
Ponderosa pine
Aspen and cottonwoods
Pinyons
Rocky Mountain and Utah junipers
Bristlecone and limbber pines
Mountain-mahogany

Southern Portion (New Mexico and Arizona):

Ponderosa pine
Douglas-fir
White, alpine, and corkbark firs
Engelmann and blue spruces
Pinyons
One-seed, alligator, and Rocky Mountain junipers
Aspen and cottonwoods
Limbber, Mexican white, and Arizona pines
Oaks, walnut, sycamore, alder, boxelder
Arizona cypress

PACIFIC COAST FOREST

Northern Portion (Western Washington and Western Oregon):

Douglas-fir
Western hemlock
Grand, noble, and Pacific silver firs
Western redcedar
Sitka and Engelmann spruces
Western white pine
Port Orford cedar and Alaska cedar
Western and alpine larches
Lodgepole pine
Mountain hemlock
Oaks, ashes, maples, birches, alders, cottonwoods, madrone

Southern Portion (California):

Ponderosa and Jeffrey pines
Sugar pine
Redwood and giant sequoia
White, red, grand, and Shasta red firs
California incense-cedar
Douglas-fir
Lodgepole pine
Knobcone and Digger pines
Bigcone-spruce
Monterey and Gowen cypresses
Sierra and California junipers
Singleleaf pinyon
Oaks, buckeye, California-laurel, alder, madrone

SOUTHERN FOREST

Pine Lands:

Shortleaf, loblolly, longleaf, slash, and sand pines
Southern red, black, post, laurel, cherrybark, and willow oaks
Sweetgum
Winged, American, and cedar elms
Black, red, sand, and pignut hickories
Eastern and southern redcedars
Basswoods

Alluvial Bottoms and Swamps:

Sweetgum and tupelos
Water, laurel, live, overcup, Texas, and swamp white oaks
Southern cypress
Pecan, water and swamp hickories
Beech
River birch
Ashes

Alluvial Bottoms and Swamps:

Red and silver maples
Cottonwoods and willows
Sycamore
Hackberry
Honeylocust
Holly
Redbay and sweetbay
Southern magnolia
Pond and spruce pines
Atlantic white-cedar

CENTRAL HARDWOOD FOREST

Northern Portion:

White, black, northern red, scarlet, bur, chestnut, and chinquapin oaks
Shagbark, mockernut, pignut, and bitternut hickories
White, blue, green, and red ashes
American, rock, and slippery elms
Red, sugar, and silver maples
Beech
Pitch, shortleaf, and Virginia pines
Yellow-poplar
Sycamore
Chestnut
Black walnut
Cottonwoods
Hackberry
Black cherry
Basswoods
Ohio buckeye
Eastern redcedar

Southern Portion:

White, post, southern red, blackjack, Shumard, chestnut, swamp chestnut, and pin oaks
Sweetgum and tupelos
Mockernut, pignut, southern shagbark, and shellbark hickories
Shortleaf and Virginia ("scrub") pines
White, blue, and red ashes
Yellow-poplar
Black locust
Elms
Sycamore
Black walnut
Silver and red maples
Beech
Dogwood
Persimmon
Cottonwoods and willows
Eastern redcedar
Osage-orange

Texas Portion:

Post, southern red, and blackjack oaks
Eastern redcedar, Ashe juniper

FLORIDA AND TEXAS FOREST—TROPICAL

Mangrove, false mangrove
Royal and thatch palms; palmettos
Florida yew
Wild figs
Seagrasses ("pigeon plum")
Blolly
Bahama lysiloma ("wild tamarind")
Wild-dilly
Gumbo-limbo
Poison-tree
Inkwood
Button-mangrove
False-mastic ("wild olive")
Fishpoison-tree ("Jamaica dogwood")

NORTHERN FOREST

Northern Portion:

Red, black, and white spruces
Balsam fir
Eastern white, red ("Norway"), jack, and pitch pines
Hemlock
Sugar and red maples
Beech
Northern red, white, black, and scarlet oaks
Yellow, paper, sweet, and gray birches
Quaking and bigtooth aspens
Basswoods
Black cherry
American, rock, and slippery elms
White and black ashes
Shagbark and pignut hickories
Butternut
Northern white-cedar
Tamarack

Southern Portion (Appalachian Region):

White, northern red, chestnut, black, and scarlet oaks
Chestnut
Hemlock
Eastern white, shortleaf, pitch, and Virginia ("scrub") pines
Sweet, yellow, and river birches
Basswood
Sugar and red maples
Beech
Red spruce
Fraser fir
Yellow-poplar
Cucumber magnolia
Black walnut and butternut
Black cherry
Pignut, mockernut, and red hickories
Black locust
Tupelos ("blackgums")
Buckeye

ALASKA FOREST

Coast Forest:

Western hemlock (important)
Sitka spruce (important)
Western redcedar
Alaska cedar
Mountain hemlock
Lodgepole pine
Black cottonwood
Red and Sitka alders
Willows

Interior Forest:

White (important) and black spruces
Alaska paper (important) and Kenai birches
Black cottonwood
Balsam poplar
Aspen
Willows
Tamarack

Figure 8.—Forest regions of the United States.

Figure 9.—Silhouettes of forest trees. When tree shadows fall on level ground, they often permit identification of individual species. (Reprinted by permission of L. Sayn-Wittgenstein, Forest Research Branch, Canada Department of Forestry.)

Figure 10.—Vertical views of tree crowns. Compare with stereograms in figure 11. (Reprinted by permission of L. Sayn-Wittgenstein, Forest Research Branch, Canada Department of Forestry.)

Figure 11.—Large-scale stereograms showing star-shaped white pine crowns (top), cone-shaped balsam fir crowns (center), and a red pine plantation surrounded by a stand of basswood (bottom). The two upper stereograms are on panchromatic film at a scale of 50 feet per inch. The bottom pair is on infrared film at a scale of 330 feet per inch. (Reprinted by permission of L. Sayn-Wittgenstein, Forest Research Branch, Canada Department of Forestry.)

Figure 12.—Summer panchromatic photography in Ontario. In the upper stereogram (No. 35) stand 1 is balsam fir and stand 2 is black spruce. In the lower stereogram (No. 66) stand 1 is aspen-white birch and stand 2 is beech. Scale is 1,320 feet per inch. (Reprinted by permission of V. Zsilinszky, Ontario Department of Lands and Forests, Canada.)

Figure 13.—Infrared stereogram illustrating forest associations in central Alaska. Types are (1) paper birch, (2) aspen, and (3) white spruce. A portion of the Alaska Railroad is shown at (4). Scale is about 420 feet per inch.

Figure 14.—USDA panchromatic stereogram from Del Norte County, Calif. Enclosed trees are primarily redwood, with lesser numbers of Douglas-fir, spruce, and hemlock. Clear stereo-viewing is hindered by the heavy displacement of trees, some of which are 250 to 300 feet tall. Scale is about 1,667 feet per inch.

Figure 15.—USDA panchromatic stereograms from Jackson (above) and Clarke Counties, Miss. At (1) is a natural stand of longleaf and slash pines; loblolly-shortleaf pines are pictured at (2) and leafless upland hardwoods at (3). Scale is about 1,667 feet per inch.

Figure 16.—USDA panchromatic stereograms from Columbia (above) and Sevier Counties, Ark. Two loblolly pine plantations are pictured at (1), while the mountainous terrain at (2) supports a mixture of upland hardwoods and short-leaf pine. Scale is about 1,667 feet per inch.

Figure 17.—USDA panchromatic stereograms from Bolivar County, Miss. The fine-textured stand at (1) is willow and cottonwood growing on a recent deposition of sand and silt. At (2) is a stand of bottom-land hardwoods, i.e., oaks, gums, maples, and other wet-site species. Scale is about 1,667 feet per inch.

Figure 18.—USDA panchromatic stereograms from Lafayette County, Ark. Pure stands of southern cypress are shown at (1); the irregular and somewhat star-shaped crowns of this species can be clearly discerned against the water. At (2) is a mixture of cypress and tupelo gum, while a pure stand of tupelo gum is pictured at (3). Scale is about 1,667 feet per inch.

quately treated in several readily available publications (1, 17, 18), it will not be reviewed here.

General Land Office (GLO) plats.—Most of the United States west of the Mississippi River and north of the Ohio River, plus Alabama, Mississippi, and portions of Florida, was originally subdivided under the U.S. Public Land Survey. Township, range, and section lines are often visible on aerial photographs. If enough such lines and corners can be identified, GLO plats can be constructed for use as base maps from field notes available at State capitals or county offices. To do this, a GLO plat showing sections, quarter sections, and forties is drawn to average photo scale from field notes. As many as possible of the same lines and corners are pinpointed on the aerial photographs, preferably arranged in a systematic framework throughout the forest property. Ownership maps, county highway maps, and topographic quadrangle sheets may help to identify such corners, but additional points must usually be found by taking the photographs into the field. The accuracy of this method depends upon the number of grid lines and corners which can be pinpointed on the aerial photographs. The technique described is adapted from Johnson (7).

When photo interpretation of forest types has been completed, the detail is transferred to the plat, one square of the grid being completed at a time. If the plat and photographs are of the same scale, transfer can be made by direct tracing on a light table; where scales differ, a vertical sketchmaster is recommended (fig. 19). By moving this instrument up or down on its adjustable legs, maps can be drawn at scales of seven-tenths to one and one-half times the scale of the contact print. The sketchmaster accommodates a single, annotated print, which is placed face up on the platform under a large mirror. Photo images are reflected from the large mirror to a semisilvered mirror in the eyepiece housing. The semitransparent eyepiece mirror thus provides a monocular view of the reflected photo image superimposed on the base map. When the grid points on photograph and map have been matched, the transfer of detail becomes a simple procedure (fig. 20).

Topographic and county maps.—Topographic quadrangle sheets and county highway maps are often useful in preparing base maps and identifying features on aerial photographs. When available, 7½-minute quadrangle maps at a scale of 1:24,000 provide excellent base maps, and can be

Figure 19.—Vertical sketchmaster for transferring detail from single contact prints to a base map. A semisilvered eyepiece mirror enables the operator to view photograph and map simultaneously. (Courtesy of Aero Service Corporation.)

purchased for about 30 cents per copy. Maps for areas west of the Mississippi River, including all of Louisiana and Minnesota, can be purchased from

U.S. Geological Survey
Distribution Section
Federal Center
Denver, Colo. 80225

For areas east of the Mississippi River, including Puerto Rico and the Virgin Islands, maps may be purchased from

U.S. Geological Survey
Distribution Section
Washington, D.C. 20240

Maps of Hawaii may be ordered at either address. All orders must be paid in advance. Other sources of topographic quadrangle maps are the Maps and Surveys Branch of the Tennessee Valley

Authority, Chattanooga, Tenn.; the Mississippi River Commission, U.S. Army Corps of Engineers, Vicksburg, Miss.; and the U.S. Coast and Geodetic Survey, Department of Commerce, Washington, D.C.

County maps, usually obtained from State highway departments, may serve as base maps when a high level of accuracy is not required. They show township, range, and section lines, in addition to geographic coordinates (longitude and latitude) to the nearest 5 minutes. They are usually printed at a scale of about one-half inch per mile. Although bearings of section lines are not shown, such maps are more reliable than oversimplified plats showing idealized sections oriented exactly with the cardinal directions. Portions of county maps can be enlarged to photo scale and sections subdivided into quarters or forties by proportionate measurement. These maps may be especially helpful in preparing GLO plats as previously outlined.

Figure 20.—Photo mosaic assembled from 1960 USDA prints, and corresponding map compiled with the vertical sketchmaster. The area is in Clarke County, Ga.

MEASURING AREAS

Both aerial and ground cruising require accurate measurement of forest areas. Photographs offer an inexpensive means of making such determinations. In locations where photo scales are not appreciably altered by topographic changes, areas can be measured directly on contact prints. Greater accuracy is possible if forest types are transferred to controlled base maps before area is determined. This procedure is essential for mountainous terrain. On the other hand, if only relative proportions of the forest types are needed and measurements are limited to the effective areas of contact prints, no bias results from using photographs, even when local relief ranges from 500 to 1,000 feet (12, 19). (This statement assumes that, for large tracts, errors in measurement of areas below the datum plane are compensated by errors of a similar magnitude above the datum plane.) Small tracts in rough topography should be measured on controlled maps. Measurement techniques are similar in both cases, so the procedures outlined for measuring area on photographs generally apply to map determinations.

Devices for area measurement.—The principal devices for area measurement are polar planimeters, transects, and dot grids.

The planimeter is relatively expensive and its use somewhat tedious. The pointer is carefully run clockwise around the boundaries of an area two or more times (for an average reading). From the vernier scale, the area is read in square inches and then converted to the desired units, usually acres, on the basis of photo or map scale.

The transect method is analogous to determining forest area by a strip cruise in which the chainage encountered in each forest type is recorded. An engineer's scale is alined on the photographs to cross topography and drainage at approximately right angles. The length of each type along the scale is recorded to the nearest tenth of an inch. Proportions for each type are developed by relating the total measure of that type to the total linear measure. For example, if six equally spaced parallel lines 6 inches long are tallied on a given photograph, the total transect length is 36 inches. If hardwoods are intercepted for a total measure of 7.2 inches, this particular type would be assigned an acreage equivalent to $7.2 \div 36$, or 20 percent of the total area. The transect method is simple and requires a minimum of equipment. For making rough area estimates on photo index sheets, special transparent overlays for location of transect lines can be improvised (9).

Use of a dot grid is the preferred method for determining area on aerial photographs. A dot grid is a transparent overlay with dots systematically arranged on a grid pattern. In use, the grid is alined with a straight-line feature to avoid positioning bias, and then dots are tallied for each

forest type (fig. 21). Type areas are calculated by proportions: the number of dots on a given type divided by the total number of dots counted yields a percentage value that is multiplied by the total area to obtain the acreage of the type. If total acreage is not known, the number of acres per square inch is determined. This figure is then divided by the number of dots per square inch to find the acreage represented by each dot.

Intensity of dot sampling.—The number of dots that must be counted for a given accuracy depends upon the estimated proportion of the total area occupied by the most important classification to be recognized. For example, suppose area breakdowns are needed for 10 square miles photographed at a scale of 1:15,840. Estimated proportions of each area classification are as follows: forest, 25 percent; agricultural lands, 60 percent; urban areas, 10 percent; and rivers and lakes, 5 percent. If the most important category is agricultural land, the dot grid intensity would be calculated on this basis. If the population being sampled is large, the number of samples may be computed by a formula based on the binomial distribution:

$$n = p(1-p) \left[\frac{t}{E} \right]^2$$

Where: n = total number of samples (dots) to be counted.

p = estimated proportion of the total area in the most important type classification (0.60 in this case).

t = a constant denoting the reliability of the estimate or level of statistical significance (the value 1.96 used here denotes a statistical probability of being correct 95 times in 100).

E = maximum permissible error, expressed as a percent of total area. (In this case, ± 2 percent or 0.02.)

Substituting the above values, we get:

$$n = 0.60(1-0.60) \left[\frac{1.96}{0.02} \right]^2 = 2,305 \text{ dots}$$

Thus if we are correct in the assumption that the true percentage of agricultural land is 60, then 2,305 dots should be spaced over the total area to insure a 95-percent probability of obtaining an estimated proportion lying between 58 and 62 percent. At the specified photo scale of 1:15,840, the total print area represented by 10 square miles would be 160 square inches. Therefore, the number of dots needed per square inch would be $2,305 \div 160$, or about 14. Here, it would be most expedient to select a square-spaced grid having 16 dots per square inch.

Figure 21.—Dot grid positioned over part of an enlarged USDA print for acreage determination. The delineated stand contains about 25 acres. Photo scale is 660 feet per inch.

The principal drawback to the formula method is that a prior knowledge of p is required, which is actually the value being sought. By definition, however, p always lies between 0 and 1, and it can be shown that $p(1-p)$ reaches a maximum value of 0.25 when p is set at 0.50 or 50 percent. Therefore, the equation may be revised to read:

$$n = 0.25 \left[\frac{t}{E} \right]^2$$

And, substituting values from the previous solution:

$$n = 0.25 \left[\frac{1.96}{0.02} \right]^2 = 2,401 \text{ dots, an increase of 96 dots over the first estimate.}$$

A grid with 16 dots per square inch will still be adequate for the desired degree of accuracy ($16 \times 16 = 2,560$ dots).

For areas of 1,000 acres or less, grids with closely spaced dots are needed. Grids with 64 dots per square inch are commonly used with 1:20,000 photographs. As 1 square inch equals 63.77 acres at photo scale, each dot represents 0.996 acres. For 1:15,840 photography (40 acres per square inch), grids having 40 dots per square inch are available. It is not essential, of course, that a separate grid be used for each photo scale or that the number of dots per square inch be equal to the acreage per square inch. Wherever feasible, the preceding equation should be used to determine the grid intensity.

TREE HEIGHT, CROWN DIAMETER, AND CROWN CLOSURE

Tree Height

Tree heights are commonly determined on aerial photographs by measuring either stereoscopic parallax or shadow lengths. Though more difficult for the beginner, the parallax method is faster, requires fewer calculations, and is more adaptable to a variety of stand conditions. Anyone who can use a stereoscope can train himself to measure stereoscopic parallax, and even the occasional interpreter will find this method of measuring heights advantageous.

Shadow-length measurements are reliable only in open-grown stands where individual shadows fall on level ground. Accurate measurement is almost impossible in dense, irregular stands or on slopes. Furthermore, the conversion of shadow length to tree height is complex in comparison to the conversion of parallax measurements. For these reasons only the parallax method will be discussed. Foresters interested in details of shadow-height calculations should refer to Johnson's article (8), which includes a special form for making tree-height conversions.

The concept of parallax.—*The Manual of Photogrammetry* (1) defines parallax as "the apparent displacement of the position of a body with respect to a reference point or system, caused by a shift in the point of observation." In measuring object heights on stereoscopic pairs of aerial photographs, two types of parallax must be measured or approximated—the absolute and the differential. The absolute stereoscopic parallax of a point is "the algebraic difference, parallel to the air base, of the distances of the two images from their respective principal points" (18). The parallax difference, or differential parallax, of an object being measured for height determination is the difference in the absolute stereoscopic parallax at the top and the base of the object, measured parallel to the air base or flight line.

The formula for converting parallax measurements to tree height on aerial photographs is:

$$h = \frac{H \times dP}{P + dP}$$

where h = height of object

H = altitude of aircraft above ground datum

P = absolute stereoscopic parallax at base of object being measured

dP = differential parallax

If object heights are to be determined in feet, the height of the aircraft (H) must also be in feet. Absolute stereoscopic parallax (P) and differential parallax (dP) must be expressed in the same units; ordinarily, these units will be thousandths of inches or hundredths of millimeters.

The height of the aircraft above ground datum

is calculated from the basic scale formula, transposed to the more convenient form: Flight altitude (H) = focal length $\times$ scale denominator. With photographs of 1:20,000 scale and a camera of 8.25-inch focal length, the flight altitude would be $0.6875 \times 20,000 = 13,750$ feet.

In flat terrain, the average photo base length is ordinarily substituted as the absolute stereoscopic parallax (P). If the ground elevation at the base of the tree being measured differs from the elevation of the principal points by more than 200 or 300 feet, however, the following method (17) should be used to calculate a new value for P :

1. Orient the stereo-pair with flight lines superimposed and images separated about 2.2 inches. Clip down photographs.
2. Measure the distance between the two principal points to the nearest 0.01 inch with an engineer's scale.
3. Measure the distance between corresponding images on the two photographs at or near the base of the tree to the nearest 0.01 inch.
4. Subtract (3) from (2) to obtain the absolute stereoscopic parallax at the base of the tree.

Differential parallax (dP) is usually measured stereoscopically with either a parallax wedge or parallax bar, employing the "floating mark" principle. Such instruments are discussed in the section that follows. The concept of differential parallax can be illustrated by direct measurement of severely displaced images such as in the large-scale stereogram of a water tank in figure 22. With a photo scale of 1:7,800 and a camera focal length of 6 inches, flight altitude above ground (H) is computed as $0.5 \times 7,800$ or 3,900 feet. Average photo base length (P) for the stereo-pair is 3.70 inches.

Absolute stereoscopic parallax at the base and top of the water tank is measured parallel to the line of flight with an engineer's scale; the difference (2.27–2.13 inches) is dP , the differential parallax of the displaced images. As the tank is somewhat tapered in form, measurements were made at the midpoint of the base and vertically above this position at the center of the top. Substituting in the parallax formula:

$$\text{Height of tank } (h) = \frac{3,900 \times 0.14}{3.70 + 0.14} = \frac{546.00}{3.84} = 142 \text{ feet}$$

Parallax wedges.—Parallax wedges are usually printed on transparent film or glass. The basic design consists of two rows of dots or graduated lines beginning about 2.5 inches apart and converging to about 1.8 inches apart. The graduations on each line are calibrated for making parallax readings to the nearest 0.002 inch. The "training wedge" in figure 23 is graduated for reading to the nearest 0.01 inch only.

Figure 22.—Large-scale stereogram showing an industrial plant and heavily displaced water tank. Measurements of stereoscopic parallax shown can be used to determine height of the tank above ground. (Courtesy of Abrams Aerial Survey Corporation.)

Figure 23.—Parallax wedge correctly oriented over a large-scale stereogram of a railroad trestle. Graduations on right-hand row of dots refer to separation of the converging lines in inches. (Courtesy of Abrams Aerial Survey Corporation.)

Figure 24.—Modern mirror stereoscope with inclined magnifying binoculars. Positioned across the two photographs is a parallax bar (stereometer) for measuring heights of objects. (Courtesy of Wild-Heerbrugg Instruments, Inc.)

The parallax wedge is placed over the stereoscopic image with the converging lines perpendicular to the line of flight and adjusted until a single fused line of dots or graduations is seen sloping downward through the stereoscopic image. If the photo images are separated by exactly 2 inches, a portion of the parallax wedge centering around the 2-inch separation of converging lines will fuse and appear as a single line. The line will appear to split above and below this section. Using the fused line of graduations, the differential parallax is obtained by counting the number of dots or intervals between the point where a graduation appears to rest on the ground and the point where a graduation appears to “float” in the air at the same height as the top of the object. In figure 23, for example, the dot resting on top of the railroad trestle yields a reading of 2.22 inches. When this value is subtracted from a ground reading of 2.26 inches, dP is determined as 0.04 inches. If flight altitude (H) of 4,000 feet and a photo base length of 3.56 inches, the parallax formula yields:

$$\text{Height of trestle } (h) = \frac{4,000 \times 0.04}{3.56 + 0.04} = \frac{160.00}{3.60} = 44 \text{ feet}$$

The interpreter should remember that the degree of stereoscopic parallax normally encountered on 1:12,000 to 1:20,000 USDA photographs is much less than that illustrated here. Nevertheless, the

principle and the methods of measurement are exactly the same. Where P is large in relation to dP , tables 2 and 3 can be used as shortcut approximations in converting parallax measurements to object heights on USDA photographs.

The parallax bar.—This instrument is more expensive than the parallax wedge and yields results of comparable accuracy. But many interpreters prefer the parallax bar because the floating dot is movable and thus easier to place on the ground and at crown levels. A parallax bar designed to measure heights with a mirror stereoscope is shown in figure 24.

The bar has two lenses attached to a metal frame that houses a vernier and a graduated metric scale. The left lens contains the fixed reference dot; the dot on the right lens can be moved laterally by means of the vernier. The bar is placed over the stereoscopic image parallel to the line of flight. The right-hand dot is moved until it fuses with the reference dot and appears to rest on the ground at the base of the tree. The vernier reading is recorded to the nearest 0.01 millimeter. The vernier is then turned until the fused dot appears to “float” at treetop level, and a second reading recorded. The difference between the readings is the parallax difference (dP) in millimeters. This value can be substituted in the parallax formula without conversion if the absolute parallax (P) is also expressed in millimeters.

Accuracy of height measurements.—Accuracy in

3.9-----	60	80	100	120	140
4.0-----	58	78	97	117	136

¹ To use table, measure parallax difference (dP) of object to nearest hundredth of a millimeter (as 0.57 mm., for example). If average photo base (P) is 3.1 inches and flight altitude is 12,000 feet, the table value of 151 is multiplied by 0.57 for an object height of 86 feet.

measuring total heights of trees and stands depends upon a number of factors, not the least of which is the interpreter's ability to determine stereoscopic parallax. Usually interpreters can detect differences in parallax of about 0.002 inch,

or 0.05 mm., and this graduation interval is used on most parallax wedges.

The interpreter who can detect a difference of 0.002 inch of stereoscopic parallax will be able to stratify forest stands into 10-foot total height classes on contact prints of 1:15,840 to 1:20,000 scales (18). Greater accuracy may be possible in flat terrain where photo scale changes are not pronounced and less skill is required in selecting the point for the base parallax reading. The ground parallax must be read on the same contour as the base of the tree.

The interpreter should consider the following points to improve accuracy in height measurement:

1. In rough terrain, a new photo scale and flight altitude should be calculated for each overlap. For stands on high ridges or in deep ravines, it is better to calculate new values for absolute stereoscopic parallax than to use the average photo base length.
2. Once a pair of photographs have been alined for stereo-viewing, they should be fastened down. A slip of either photograph between the parallax reading at the base and the top of a tree may cause highly inaccurate height readings.
3. To avoid single measurements of high variability, several measurements should be made of the same tree or stand and the results averaged.

Tree Crown Diameter

For most conifers and many hardwoods, tree crown diameter is related to stem diameter. It is thus a useful photographic measurement when estimating individual tree volumes or stand-size classes. Actual determination of crown diameter is a distance measurement, somewhat complicated by the small sizes of tree images and the effects of crown shadows.

Crown diameters are measured with either wedges or dot-type scales reading in thousandths of an inch. With a crown wedge, the diverging lines are placed tangent to both sides of the crown for making the reading. Dot-type scales have circles of graduated sizes for direct comparison with tree crowns (fig. 25). For converting measurements, the scale of photography is calculated in feet per thousandth of an inch. At 1:20,000, each 0.001 inch of crown measure equals 1.667 feet. A reading of 0.010 inch would imply a crown diameter of 17 feet (table 4).

Tree crowns are rarely circular, but, because individual limbs are often invisible on aerial photographs, they usually appear roughly circular or elliptical. Since only the parts visible from above can be evaluated, photo measures of crown diameter are often lower than ground checks of the same trees. Nevertheless, most interpreters can determine average crown diameter with reasonable precision if they take several readings.

CROWN DIAMETER SCALE
CENTRAL STATES FOREST EXPERIMENT STATION

Figure 25.—Dot-type scale for measuring crown diameters. Such scales are usually printed on transparent film.

Obviously, crown diameter measurements of individual trees are most accurate in open-grown stands. In dense stands, measurements are generally confined to determination of an average for the dominant trees. Crowns of mature conifers can usually be classified into 5-foot classes without difficulty (18).

Tree Crown Closure

Crown closure percent, also referred to as crown density, is the proportion of the forest canopy occupied by trees. Crown density may refer to all crowns in the stand regardless of canopy level or only to the dominants. Estimates are purely ocular, and stands are commonly grouped into 10-percent density classes. Printed density scales (fig. 26) may aid the interpreter, though the patterns of black dots on a white background bear little resemblance to photographic images of trees. Comparative stereograms illustrating various stand densities have also proved useful (fig. 27).

Evaluation of crown closure is much more subjective than the determination of tree height or crown diameter. Actual measurement is virtually

CROWN DENSITY SCALE

Figure 26.—Density scale for comparison with photo images in estimating crown closure percent.

impossible on most USDA photographs, and accuracy is thus dependent on the interpreter's judgment. Inexperienced interpreters tend to overestimate closure by ignoring small stand openings or including portions of crown shadows. Devices for checking closure on the ground fail to provide estimates that are truly comparable to those made on vertical photographs. Thus the neophyte must rely on practice, checked by skilled interpreters, to develop proficiency.

Crown closure is useful because of its relation to stand volume per acre. It is applied in lieu of basal area or number of trees per acre, as these cannot be accurately determined on available photography. Measurements of crown diameter and estimates of closure should always be made under the stereoscope.

Tree counts.—Complete tallies of individual trees can seldom be made accurately on available USDA photographs. In dense stands, suppressed trees and many intermediates cannot be seen. Clumps of two or three trees often appear as single

crowns, and ragged individual crowns may look like two trees. Only in even-aged, open-grown forests can all trees in a stand be separated. Counting all trees on a plot is tedious, and this

measure of density is seldom used. Where large-scale photographs are available (1:1,000 to 1:5,000), individual-tree counts may be much more reliable.

AERIAL CRUISING

Individual Tree Volumes

Ordinary tree volume tables can be easily converted to aerial volume tables when correlations can be established between tree crown diameters and stem diameters (10). The photographic determinations of crown diameter and total tree height are merely substituted for the usual field measures of stem diameter (d.b.h.) and merchantable height, respectively (fig. 28). Photographic measurements are usually limited to well-defined open-grown trees, and crown counts are required to obtain total volume for a given stand of timber.

The construction and application of aerial tree volume tables depends on a well-established relationship between photographic measures of crown diameter and ground determinations of tree d.b.h. Such relationships can often be established for individual species or species groups, notably even-aged conifers in the middle diameter classes (18). By contrast, stem-crown diameter correlations rarely have been used for estimating volumes of mixed hardwoods.

The aerial tree table (table 5) provides volumes in terms of gross cubic feet. In making an aerial

cruise, photographic measurements may include all trees on 0.2- to 1-acre circular plots, or stands may be delineated according to height classes for determination of the average tree per unit area. In the latter instance, a tree count must be made to obtain the total stand volume.

In general, the individual-tree approach to aerial cruising is of limited value when the interpreter is restricted to use of 1:12,000 to 1:20,000 USDA photographs. At this scale, images are usually too small for accurate assessment of individual trees.

Stand Volume Per Acre

If recent photographs and reliable aerial stand-volume tables can be obtained, average stand volume per acre can be estimated with a minimum of field work. Estimates are made in terms of gross volume, as amount of cull or defect cannot be adequately evaluated. Even-aged stands of simple species structure are best suited for this type of estimating, especially if gross and net volumes are essentially identical. All-aged stands of mixed hardwoods are more difficult to assess, but satisfactory results can be obtained if field checks are made to adjust the photographic estimate of stand volume per acre and to determine allowance for defect. Though volumes from photographs cannot be expressed by species and diameter classes, total gross volumes for areas as small as 40 acres can be estimated within 10 to 15 percent of volumes derived from conventional ground cruises (13).

Most aerial stand-volume tables for mixed species are constructed in terms of cubic feet per acre. Tables for species in pure stands, such as Douglas-fir, may be expressed either in board feet or cubic feet per acre. Three photographic measurements of the dominant stand are generally required for entering an aerial stand volume table: average total height, crown diameter, and crown closure percent.

Aerial volume tables have been constructed for many of the important timber associations in the United States. Included here are tables for Douglas-fir (table 6), Rocky Mountain conifers (table 7), and Kentucky hardwoods (table 8). Composite tables, applicable in mixed stands, are presented for northeast Mississippi (table 9) and for northern Minnesota (table 10). Crown diameter was eliminated as a variable in tables 6 and 10.

¹ Based on 342 trees in Arkansas, Louisiana, and Mississippi. Gross volumes are inside bark and include the merchantable stem to a variable top averaging 6 inches i.b. Reprinted from (4).

One of the several procedures for making aerial volume estimates is as follows:

1. Outline tract boundaries on the photographs, utilizing the effective area of every other print in each flight line. This assures stereoscopic

coverage of the area on a minimum number of photographs and avoids duplication of measurements.

2. Delineate all forest types. Except where type lines define stands of relatively uniform stocking and total height, they should be further broken down into homogeneous units so that measures of height, density, and crown diameter will apply to the entire unit. Generally it is unnecessary to recognize stands smaller than 5 to 10 acres.
3. Determine the acreage of each condition class with dot grids. This determination can often be made on contact prints.
4. By stereoscopic examination, measure the variables for entering the aerial stand volume table. From the table, obtain the average volume per acre for each condition class.
5. Multiply gross volumes per acre from the table by condition class areas to determine gross volume.
6. Add class volumes for the total gross volume on the tract.

A practical application is illustrated by the stereogram in figure 29 and the corresponding cordwood volume summary. In this particular inventory, hardwood components in each stand were ignored, and estimates were derived only for pine timber. The aerial cruise, fortified by fre-

¹ Gross volume, in trees 5.0 inches and larger, from stump to top limit of 4.0 inches diameter inside bark. Reprinted from (15).

² Average height of dominants and codominants as measured in the field.

³ Average estimates of several experienced interpreters includes all trees in the major canopy (occasionally excludes small trees definitely below the general canopy).

¹ Gross volumes are inside bark and include all trees 5.0 inches d.b.h. and larger from stump to a variable top diameter not less than 4.0 inches i.b. Volumes may be converted to rough cords per acre by dividing by 80.

² Based on 50 1-acre plots in Carlton County, Minn. Heavy lines indicate limits of basic data. Reprinted from (5).

quent field checks, was within 10 percent of a ground inventory made by an independent agency.

Adjusting volumes by field checks.—When aerial volume tables are not sufficiently reliable for acceptance of pure photographic estimates and allowance must be made for defective trees, some of the plots interpreted should be mechanically selected for field measurement. For example, if 350 plots were interpreted and every 10th plot selected, 35 plots would be visited in the field. If the field volumes averaged 600 cubic feet per acre as opposed to 800 cubic feet per acre for the photo plots, the adjustment ratio would be $600 \div 800$ or 0.75. If the 35 field plots are representative of the total, the ratio can be applied to the average photo volume per acre to determine the adjusted volume. Ratios should be computed by forest types, because hardwoods are likely to require larger adjustments than conifers.

The accuracy of aerial cruises depends not only upon the volume tables but also on the availability of recent photographs and the interpreter's ability to measure correctly. This last item may be the greatest single source of error. Each photo variable should be measured twice for an average, or two interpreters should assess each plot.

Photo estimates of pine cordwood volumes for a tract in the Georgia Piedmont ¹

County: Oconee

Photo No.: BQ-3BB-85, 86

Owner: J. Reynolds

Photo date: 11-1-60

Pine area: 177 acres

Scale: 1,667 ft./inch

Pine stand ²	Stand area	Total height	Crown diameter	Crown closure	Pine volumes per acre		Stand volume
	Acres	Feet	Feet	Per-cent	Cubic feet	Cords	Cords
1-----	18	40	10	25	380	4.75	85.5

11-----	12	30	10	15	190	2.37	28.4

Total pine volume (cords)..... 745.5

¹ Cubic volumes derived from table 9 and divided by 80 for conversion to cords.

² Stands are numbered as in figure 29.

Figure 29.—USDA panchromatic stereogram of a forest area in the Georgia Piedmont. Area and pine volume estimates were made for each of the stands numbered. Scale is about 1,667 feet per inch.

PHOTO STRATIFICATION FOR GROUND CRUISING

A photo-controlled ground cruise combines the features of both aerial and ground estimating, offering a means of obtaining timber volumes with maximum efficiency. Photographs are used for area determination, for allocation of field samples by forest type and stand-size classes, and for designing the pattern of field work. Tree volumes, growth, cull percents, form class, and other data are obtained on the ground by conventional methods. A photo-controlled cruise may increase the efficiency, while reducing the total cost, of an inventory on tracts as small as 100 acres.

The approach to an inventory of this kind depends largely on the types of strata recognized and the method of allocating field samples. Cost and the statistical accuracy required determines the total number of field samples to be measured. Once this number has been determined, there are several ways in which the samples may be distributed among various photo classifications:

1. By area of each class. Though sometimes used, this method is often unsatisfactory because stands of low value may occupy the greatest acreage while high-value stands may be insufficiently sampled. The opposite extreme may result if value alone (volume-per-acre classes) is used.
2. By applying different cruising intensities to each class. A 20-percent cruise might be used for high-value stands, 10 percent for medium value, and 5 percent or less for low-value areas. This arbitrary method is better than using acreage alone, but it may not be the most economical and efficient.
3. By statistical methods. A preliminary cruise or a good estimate of the variability within each class must be made before the required number of plots per class can be computed. This approach is best for large tracts; for small ones it may be costly or unwieldy.

4. By a combination of area and value (volume). This is the preferred approach for small areas. A suggested procedure adopted from Johnson (6) and Spurr (18) follows.

Plot allocation by area and volume.—Assume that the tract is 1,600 acres and that 400 field plots are to be distributed among three forest types (pine, pine-hardwood, and hardwood) and three volume classes within each type (5, 8, and 12 cords per acre).

1. Stratify each forest type into volume-per-acre classes on the basis of personal experience or with aerial stand-volume tables. Precision is not required, as the volume classes are used only as a guide. Tabulate by type and acreage:

Cords per acre	Pine (acres)	Pine- hardwood (acres)	Hardwood (acres)
5-----	120	200	100
8-----	100	500	350
12-----	80	100	50
Total-----	300	800	500

2. Multiply the number of acres in each class by the cord volume per acre. The product is the number of cords per class:

Pine	Pine-hardwood	Hardwood
5×120= 600	5×200=1,000	5×100= 500
8×100= 800	8×500=4,000	8×350=2,800
12× 80= 960	12×100=1,200	12× 50= 600
2,360	6,200	3,900

3. Add the cordage in each class to get the total for the entire area: 2,360+6,200+3,900=12,460 cords. Divide by the number of plots to get the number of cords to be represented by each plot:

$$\frac{12,460}{400} = 31.15 \text{ cords per plot}$$

4. Divide the volume for each class (item 2) by the cord volume per plot to get the number of plots assigned to each class. Round to the nearest whole number. Add the plots for each class to make sure the total (400) is correct.

Pine	Pine-hardwood	Hardwood
$\frac{600}{31.15} = 19.26(19)$	$\frac{1,000}{31.15} = 32.10 (32)$	$\frac{500}{31.15} = 16.05(16)$
$\frac{800}{31.15} = 25.68(26)$	$\frac{4,000}{31.15} = 128.41(128)$	$\frac{2,800}{31.15} = 89.88(90)$
$\frac{960}{31.15} = 30.82(31)$	$\frac{1,200}{31.15} = 38.52 (39)$	$\frac{600}{31.15} = 19.26(19)$
(76)	(199)	(125)
Total: 400 plots		

Arrangement of ground samples.—If type boundaries have been accurately delineated and stands are homogeneous within the recognized classes, field plots can sometimes be taken along routes of easy travel without introducing much bias. Usually, though, it is necessary to lay out line-plot or strip cruises at right angles to topography. The cruise lines should be drawn to scale on a type map in such a way that the required number of samples within each class can be obtained. The number of plots or chains of strip that a crew can complete per day is the basis for calculating the lengths of the lines. To minimize travel, lines may be triangular or U-shaped, beginning and ending near the same starting point on a road or trail. Compass bearings and distances can be determined on the map to avoid location bias in the field. The cruise lines can then be placed on the photographs for use in the field, if desired.

Field measurements are taken by conventional procedures. Cumulative tally sheets or point-sampling may be employed to speed the tree tally. After the cordage per acre for each volume class has been determined by field sampling, the values are multiplied by the appropriate stand acreages. The result is the total volume on the tract, by forest types:

Assumed volume class (cords per acre)	Field plots (number)	Field volumes per acre (cords)	Type area (acres)	Volume per class (cords)
PINE TYPE				
5-----	19	3.9	120	468.0
8-----	26	8.2	100	820.0
12-----	31	11.3	80	904.0
Total-----	76		300	2,192.0

PINE-HARDWOOD TYPE				
5-----	32	5.8	200	1,160.0
8-----	128	7.7	500	3,850.0
12-----	39	14.1	100	1,410.0
Total-----	199		800	6,420.0

HARDWOOD TYPE				
5-----	16	4.7	100	470.0
8-----	90	8.6	350	3,010.0
12-----	19	13.5	50	675.0
Total-----	125		500	4,155.0

ACKNOWLEDGEMENTS

Special thanks goes to Jim Von Loh who started and performed most of the RSGIG work on this project and report (and took the ground photographs) but who has since moved on to other endeavors. After departure, he continued to support the project by reviewing and commenting on this report. Also, thanks to all the field crews who spent endless time picking cinders out of shoes and walking on sharp lava: Monica Hansen, Jon Hellison, Don Robinson, Mimi Murov, Marisa Howe, Keith Pohs, and Mar-Elise Hill. Thanks to Keith Pohs, Charles Drost, Trevor Persons, and Bill Hudson for contributing to geology and wildlife sections of the report. Thanks to the park staff at Sunset Crater Volcano National Monument and at the headquarters office for quickly helping out with logistics, permitting, attending meetings, and for allowing us special permission to hike on Sunset Crater. We express special thanks to Heather Folger who put many hours into formatting this report.

SUMMARY

Sunset Crater Volcano National Monument (SUCR) Vegetation Mapping Project was initiated in the spring of 1999 as part of and in accordance with the U.S. Geological Survey-National Park Service (USGS-NPS) Vegetation Mapping Program and was completed in the spring of 2004. The Vegetation Mapping Program is administered jointly by the Center for Biological Informatics (CBI), Biological Resources Discipline (BRD) of the USGS, Denver, Colorado, and was initiated as part of the NPS Inventory & Monitoring Program. The primary goal of the Vegetation Mapping Program is to classify, describe, and map vegetation for approximately 250 NPS units.

This mapping project was performed by the following organizations under contract to the CBI:

- The Remote Sensing and GIS Group (RSGIG), Technical Service Center, Bureau of Reclamation (BOR), Department of Interior, Denver, Colorado
- The Colorado Plateau Research Station (CPRS), Southwest Biological Science Center (SBSC), USGS, Flagstaff, Arizona
- NatureServe, Boulder, Colorado

Sixteen vegetation map classes with five modifiers, three land cover map classes, and six Anderson Level II land-use map classes were used for interpretation of approximately 18,750 acres encompassing the monument (~3,040 acres) and surrounding environs (15,710 acres). Vegetation map classes were determined through extensive field reconnaissance, data collection, and analysis in accordance with the National Vegetation Classification Standard (NVCS). The vegetation map was created from photographic interpretation of 1996, 1:12,000 scale color infrared aerial photographs (0.5 hectare minimum mapping unit). All vegetation and land-use information was then transferred to a GIS database using the latest grayscale USGS digital orthophoto quarter-quads (DOQQs) as the base map and a combination of on-screen digitizing and scanning techniques. Overall thematic map accuracy for the entire mapping effort was assessed at 70.3% using the acceptable error criteria with a Kappa Index of 68.0%. The overall 90% confidence interval is 69.0% to 84.0%.

Final products are presented in this report and on the accompanying CD-ROM (Appendix A).

- FGDC-compliant Metadata

SUCR and similar National Park vegetation mapping databases can be accessed at the USGS-NPS website: <http://biology.usgs.gov/npsveg>.

1. INTRODUCTION

The Vegetation Mapping component of the NPS Inventory and Monitoring Program is a cooperative effort by the U.S. Geological Survey (USGS) and the National Park Service (NPS) to classify, describe, and map vegetation communities in more than 270 national park units across the United States.

The vegetation mapping efforts are an important part of the NPS Inventory and Monitoring Program, a long-term effort to develop baseline data for all national park units that have a natural resource component. Project activities are based on peer-reviewed, objective science. Comprehensive vegetation information is provided at national and regional levels, while also serving local management needs of individual parks. Stringent quality control procedures ensure that products are accurate and consistent for initial inventory purposes and replicable for monitoring purposes. The spatially enabled digital products produced by these efforts are available on the World Wide Web (<http://biology.usgs.gov/npsveg>).

The goals of these vegetation mapping projects are to provide comprehensive mapping of NPS vegetation resources that:

1. Is highly accurate
2. Meets scientific and FGDC standards
3. Has a nationally consistent, hierarchical, classification scheme
4. Has a level of detail useful to park management
5. Uses existing data when appropriate

This report details the park vegetation mapping study for Sunset Crater Volcano National Monument (SUCR) under the USGS-NPS Vegetation Mapping Program. The vegetation study for SUCR includes these components:

1. Collection and analysis of vegetation data
2. Creation of vegetation and mapping classifications based on the National Vegetation Classification Standard (NVCS)
3. Development of a spatial database of the SUCR vegetation using aerial photography and Geographic Information System (GIS) techniques
4. Production of final products including digital and hard copy vegetation maps, assessed to be at least 80% accurate

Because producing an accurate, detailed, digitized vegetation map is a complicated undertaking, several government agencies and private organizations were involved in the project's successful completion.

The Remote Sensing and Geographic Information Group (RSGIG), United States Bureau of Reclamation (USBR), Denver Federal Center, Lakewood, Colorado¹:

¹ The Remote Sensing and Geographic Information Group, organized in 1975, provides assistance and advice regarding the application of remote sensing and geographic information systems (GIS) technologies to meet the spatial information

1) attended planning meetings, 2) conducted aerial photosignature field review and observation point data collection, 3) provided aerial photointerpretation, 4) attended a vegetation classification map class development meeting, 5) created the GIS vegetation database and 6) provided support and content for the final report.

The Southwest Biological Science Center (SBSC), Colorado Plateau Research Station (CPRS), USGS-BRD, Flagstaff, Arizona¹ 1) attended planning meetings, 2) conducted field data collection and analysis, 3) provided data analysis and classification, 4) prepared the vegetation classification key and descriptions, 5) provided accuracy assessment data collection and analysis, 6) conducted the vegetation map accuracy assessment, and 7) prepared the final project report.

NatureServe's Western Regional Office in Boulder, Colorado² provided a review of CPRS vegetation data analyses and CPRS local vegetation descriptions as well as prepared global descriptions for the vegetation associations determined at SUCR.

¹ The Colorado Plateau Research Station is one of four research stations within the Southwest Biological Science Center. This research station was originally established in 1989 as a National Park Service Cooperative Park Studies Unit at Northern Arizona University in Flagstaff and was merged into the USGS Biological Resources Discipline in 1996. Major categories of research include ecoregional studies and conservation planning; endangered species studies; vegetation distribution, ecology, and dynamics; data management and dissemination; inventory and monitoring studies; and wildlife ecology.

² NatureServe has its roots in The Nature Conservancy (TNC), which in 1974 began establishing and supporting state natural heritage programs. By 1994 the natural heritage programs expanded significantly and The Nature Conservancy established a new network, the Association for Biodiversity Information. Now known as NatureServe, it has assumed in managing the National Vegetation Classification (NVC) and providing scientific and technical support to the network. The NatureServe network now includes 74 independent natural heritage programs and conservation data centers across the Western Hemisphere.

2. PROJECT AREA

Sunset Crater Volcano National Monument (SUCR) was authorized by Congress and the proclamation was signed by President Herbert Hoover in 1930. This 3,040-acre unit features the geologically young and approximately 8,029 ft (2,447 m) high Sunset Crater cinder cone (NPS 1997). SUCR lies approximately 13 miles northeast of Flagstaff, Arizona and is reached via U.S. Highway 89 north of Flagstaff (Figure 1). The monument is best known for extensive geologic processes and exposures relating to volcanism (i.e., cinder cones, cinder beds, and lava flows). Recreational and educational activities include hiking, scenic drives and vistas, wildlife viewing, visitor natural history education, and research opportunities. In addition to the monument, a buffer or environs of approximately 15,710 acres (6,360 hectares) of surrounding USDA Forest Service (USDA-FS) lands and privately owned residential land is also included in the project. The total project area is 18,750 acres (7,590 hectares) (Figure 2).

Figure 1. Location of Sunset Crater Volcano National Monument.

Figure 2. SUCR project boundaries and land ownership.

Location and regional setting

SUCR is situated on the southwestern Colorado Plateau of north-central Arizona, within the San Francisco Peaks Volcanic Field (Cordasco et al. 1998, Zion Natural History Association 1985). It is bounded on the north by O’Leary Peak, Robinson Mountain, Darton Dome, and Black Mountain; to the south by Lenox Crater, Little Cinder Basin, and Double Crater; on the east by Kana-a Wash; and on the west by Bonito Park and U S Highway 89. Access is provided by U.S. Highway 89, as well as county roads and USDA-FS roads through the adjacent Coconino National Forest. The NPS Visitor Center is on USDA-FS managed land just west of the monument at the edge of Bonito Park, and a Visitor Contact Station is maintained at the Bonito Lava Flow inside SUCR. A number of hiking trails and scenic overlooks are maintained in the monument and adjacent project area for visitor access and include the Lava Flow Nature Trail, Lenox Crater Trail, Bonito Park Overlook, Cinder Hills Overlook, and Painted Desert Vista.

Climate

SUCR has a semi-arid, continental climate that includes moderately hot, moist summers and cold, dry winters (Appendix B). Precipitation events, often in the form of violent thunderstorms, occur from July through September. For example, during 1997, NOAA records show that 45% of the annual 20 inches of precipitation fell during this three-month period (Cordasco et al. 1998, NOAA 1997). Summer maximum temperatures range between 80-95 degrees F., while winter minimum temperatures may reach down to -25 degrees F. The prevailing winds are southwesterly.

Geology and topography

SUCR lies near the northeastern edge of the San Francisco volcanic field, which covers approximately 1,800 square miles of the southern Colorado Plateau in north-central Arizona (Priest et al. 2001). The volcanic field, whose major feature is the 12,600 foot high San Francisco Peaks, formed during the latter part of the Cenozoic era. Lava flows, cinders, tuffs, and other volcanic units are well exposed throughout the monument (NPS 1997 and Zion Natural History Association 1985). The monument's namesake landform, Sunset Crater (Figure 3), a cinder cone, is a relatively recent landscape feature that formed during an eruption period that began sometime between 1040 and 1100 A.D. (Ort et al. 2002). This period of activity, was short-lived from a period of days to years, blanketed much of the surrounding area in a thick bed of cinders and produced two contemporaneous lava flows, the Kana-a and the Bonito flow (Ort et al. 2002) (Figure 4).

Figure 3. Sunset Crater cinder cone (foreground) and San Francisco Peaks (background).

Figure 4. Bonito Lava Flow inside Sunset Crater Volcano National Monument.

The volcanic units comprising the San Francisco Peaks Volcanic Field overlie a sequence of ancient, sedimentary rock formations. These Precambrian and Paleozoic strata are the same or similar units seen in the Grand Canyon to the northwest (Chronic 1988). Many of the sedimentary rocks underlying the region formed in a number of environments associated with an ancient sea. Sandstones formed as outwash deposited on low-lying plains or as remnants of ancient sand dunes, and shales and limestones formed as the region was periodically submerged under a transgressing sea (Zion Natural History Association 1985). Subsequent uplift of this massive sequence of rocks promoted erosion that later exposed several of these older sedimentary units. These are most readily seen in the Painted Desert to the north and east of SUCR, but also can be seen in other localities to the west and south.

The SUCR landscape contains outcrops and slopes of both basalt and more silicic rocks, exposed beds of volcanic tuff, some with high iron concentrations, aa lava flows, and cinder hills and beds ranging from black to reddish brown in color (Figure 5). Because of northern Arizona's relatively cool dry climate, Sunset Crater and other volcanic features of the monument have not weathered significantly since their formation. The porous nature of the cinders resists furrowing by runoff. However, lichens now cover much of the lava, and areas of vegetation occur in pockets where humus has built up from wind-blown pine needles, cinders, and decayed plant matter.

Figure 5. Black cinder beds and adjacent cinder cone, Lenox Crater, among ponderosa pine trees and apache plume shrubs.

Figure 6. Shaded relief map of the project area.

Topography of SUCR consists of steep peaks, rolling hills, slopes, broad flats, and small drainages (Figure 6). The elevations of several prominent landscape features are as follows: O'Leary Peak (2,355m/8,940ft), Darton Dome (2,560m/8,410ft), Black Mountain (2300m/7,555ft), Robinson Mountain (2,400m/7,911ft), Sunset Crater (2,450m/8,039ft), and Lenox Crater (2,210m/7,250ft). Lower elevation flats include Kana-a Wash (2,040m/6,700ft), Bonito Park (2,100m/6,900ft), and just outside the monument boundary, Cinder Lake (2,010m/6,660ft). Though the cinders, lava flows, and cinder cone of Sunset Crater are the park's major features, other volcanic landforms are evident, in particular O'Leary Peak and Darton Dome, two steep-sided dacite domes along the park's northern boundary.

Wildlife

The ponderosa pine (*Pinus ponderosa*) woodland that covers much of SUCR strongly influences the fauna of the area. This is particularly true for the birds, with many of the most common and most conspicuous species at the monument being those typical of ponderosa pine woodlands. Such species include Lewis' Woodpecker (*Melanerpes lewis*), Steller's Jay (*Cyanocitta stelleri*), Mountain Chickadee (*Parus gambeli*), Pygmy Nuthatch (*Sitta pygmaea*), Yellow-rumped Warbler (*Dendroica coronata*), and Grace's Warbler (*Dendroica graciae*). Other common and frequently seen small birds in and around the monument include Williamson's Sapsucker (*Sphyrapicus thyroideus*), Pinyon Jay (*Gymnorhinus cyanocephalus*), Clark's Nutcracker (*Nucifraga columbiana*), Western Bluebird (*Sialia mexicana*), Western Tanager (*Piranga ludoviciana*), and Dark-eyed Junco (*Junco hyemalis*). Among larger birds, the most commonly seen species are Common Raven (*Corvus corax*), Turkey Vulture (*Cathartes aura*), and Red-tailed Hawk (*Buteo jamaicensis*). Occasional Golden Eagles (*Aquila chrysaetos*) may be seen at any time of year, and Bald Eagles (*Haliaeetus leucocephalus*) are present in small numbers during the winter.

The most conspicuous small mammal at the monument, the Abert's squirrel (*Sciurus aberti*), is also closely associated with ponderosa pine for both food and nest sites. Although not as frequently seen, porcupines (*Erethizon dorsatum*) are also fairly common and frequently found in ponderosa pine. Other common small mammals include desert cottontail (*Sylvilagus audubonii*), deer mouse (*Peromyscus maniculatus*), and pinyon mouse (*P. truei*). Among larger mammals, there are a variety of small and medium-sized carnivores in and around SUCR. Most frequently seen are coyotes (*Canis latrans*) and raccoons (*Procyon lotor*), particularly around the campground and housing area. The gray fox (*Urocyon cinereoargenteus*), bobcat (*Lynx rufus*), striped skunk (*Mephitis mephitis*) and long-tailed weasel (*Mustela frenata*) are also present. Black bears (*Ursus americanus*) and mountain lions (*Felis concolor*) are both present at least occasionally, but are rarely seen. Among ungulates, mule deer (*Odocoileus hemionus*) are the most common native species at SUCR. Elk (*Cervus elaphus*) were not originally native to northern Arizona, but introduced animals have expanded into the area and small numbers are now seen seasonally. Herds of pronghorn (*Antilocapra americana*) occur in grasslands and one-seed juniper (*Juniperus monosperma*) savannas at lower elevations, and migrate seasonally to the vicinity of SUCR. Javelina (*Pecari tajacu*) are a new addition to the mammal list. This species has been expanding its range northward from southern and central Arizona, and individuals have recently been recorded within the monument boundaries.

The amphibian and reptile fauna at SUCR is depauperate, because of the relatively high elevation and dry conditions. No amphibian species have been positively documented at the monument, though there is an unconfirmed report of tiger salamander (*Ambystoma tigrinum*). The most conspicuous lizard species in and around the monument are the eastern fence lizard (*Sceloporus undulatus*) and tree lizard (*Urosaurus ornatus*). The greater short-horned lizard (*Phrynosoma hernandesi*) and plateau striped whiptail (*Cnemidophorus velox*) are also present, but are not as frequently seen. Only two snakes are known from the immediate area of the monument: the gopher snake (*Pituophis melanoleucus*) and the western rattlesnake (*Crotalus viridis*); although both are rare at this elevation.

Vegetation

Vegetation of SUCR and its environs is diverse, including nearly barren beds of cinder or lava and rock outcrops, to grassy meadows, open stands of trees with sparse understory shrublands, and dense forests on more moist aspects of the highest slopes, drainages, and ridges (Figure 7). SUCR is probably most noted for the sparsely vegetated cinder cones, lava beds, and lava rock outcrops. Most of these geologically dominated landform features consist of very sparse to no vegetation and cover approximately 20% of the project area.

Woodlands, which are open forest canopies, dominate the project area and occur on flats, slopes, hills, drainages, and ridges. The most common tree species in the project area is ponderosa pine (*Pinus ponderosa*). Ponderosa pine woodlands are typically found on cinder soils with little to no understory cover. Ponderosa pine may be present in nearly pure stands or may intermix with other coniferous trees common to the area, including Douglas-fir (*Pseudotsuga menziesii*), limber pine (*Pinus flexilis*), pinyon pine (*Pinus edulis*), and Utah juniper (*Juniperus osteosperma*). The second most common tree species is pinyon pine and often co-occurs with Utah juniper. Limber pines and Douglas-fir are confined to a mixed conifer zone on O'Leary Peak and Darton Dome. Small stands of quaking aspen (*Populus tremuloides*) are present throughout the project area. Quaking aspen grow along the edges of lava beds, within the lava beds, and in small stands on O'Leary Peak and Darton Dome, often adjacent to stands of Douglas-fir.

Shrublands occur mainly in small patches on rock outcrops, on sparse cinder slopes, in the openings of woodland canopies, and can co-dominate with grasses in open meadows. Shrublands are rarely observed without seedling or sapling trees present. The most widely distributed and common shrub is Apache plume (*Fallugia paradoxa*); it occurs on sparse cinder slopes and is also a common understory shrub. Other shrubs which dominate small stands or patches in lava outcrops, on scree, and rock outcrops include rabbitbrush (*Ericameria nauseosa*), three-leaved sumac (*Rhus trilobata*), ocean spray (*Holodiscus dumosus*), pericome (*Pericome caudata*), brickellbush (*Brickellia californica*), and wax currant (*Ribes cereum*).

Figure 7. Vegetation typical of SUCR includes A) islands of vegetation in lava beds, B) sparsely vegetated cinder barrens, C) grassy meadows within surrounding woodlands, D) sparse shrub understory in open woodlands and E) and F) dense forests at higher elevations.

Grasses commonly occur as the understory in tree canopies, in smaller patches between tree canopies, as well as in more open meadow-like areas. Blue grama (*Bouteloua gracilis*) and mountain muhly (*Muhlenbergia montana*) are the dominant species in these grassland areas.

Blue grama is the most common grass species. It occurs in larger meadows or parks, such as Bonito Park (an open-grassland area west of SUCR that is co-managed by the USDA-FS) and often is in vegetation co-dominated by rabbitbrush (*Ericameria nauseosa*). Less common in the grassland patches are western wheatgrass (*Pascopyrum smithii*) and sand bluestem (*Andropogon hallii*). Sand bluestem is a bunchgrass that occurs mostly in sparse patches in the eastern section of the project area. Western wheatgrass is often used in re-seeding efforts (FEIS 2001) and is found mainly in the recently burned areas northwest of the monument. Disturbed areas also facilitate introduced annual grasses, particularly cheatgrass (*Bromus tectorum*), native forbs such as meadow-rue (*Thalictrum fendleri*) and Carruth's sagewort (*Artemisia caruthii*), and non-native species such as toadflax (*Linaria dalmatica ssp. dalmatica*) and mullein (*Verbascum thapsus*).

Land use

Various types of land use occur in the project area today; however, mapped land use (including transportation, communication, and utility areas; facilities; residential land; reservoirs and trick tanks; strip mines, quarries, and gravel pits; and croplands and pastures) covers less than 1% of the project area (480 acres). Historically pioneers altered the landscape for agricultural activities, resulting in remnant historic agricultural fields that are visible on the aerial photography.

Current land use includes access/recreational roads and trails, monument and USDA-FS facilities, pumice quarry sites, residences, and limited amounts of agricultural activity. Pumice is mined to incorporate into soap products and is also used in the stone-washed blue jean manufacturing process. U. S. Highway 89 was widened through the project area during the course of the study, resulting in land use changes that are not evident on the 1996 aerial photos used in this project.

South of the monument, off-highway vehicle (OHV) use on cinder beds is heavy, resulting in unsightly tracks, damage to, and in some cases elimination of, sparse vegetation, and introduction sites for exotic plant species including knapweed (*Centaurea* spp.). OHV tracks, as seen on the 1996 aerial photographs, were mapped. These tracks are constantly changing and it is likely that they will need to be re-evaluated for current extent of OHV use in and around the monument. Residential housing in the southern section of the project environs, specifically Lenox Park, has also increased since the 1996 aerial photography was acquired. A controlled burn also occurred in the project environs since 1996, possibly changing understory species composition and density as delineated in the photography.

3. METHODS

In mapping and classifying the vegetation of SUCR, we used the protocols and procedures established by the USGS/BRD (Appendix C) and described in *Field Methods for Vegetation Mapping, Standardized National Vegetation Classification System* (TNC and ERSI 1994a). The general work tasks were:

1. Project scoping and planning
2. Existing information review
3. Preliminary data collection
4. Aerial photography and base map acquisition
5. Sampling design development
6. Field data collection
7. Vegetation classification and characterization
8. Vegetation map preparation
9. Accuracy assessment

Project scoping and planning

SUCR vegetation mapping incorporated the combined expertise and oversight of several organizations: 1) oversight and programmatic considerations were managed by the Center for Biological Informatics (CBI) of the USGS/BRD, 2) NPS and SUCR personnel provided additional guidance on specific monument needs, 3) aerial photointerpretation and cartographic mapping were provided by the USBR/RSGIG, 4) the CPRS provided field data collection, data analysis, the plant association local descriptions and key, and accuracy assessment, and 5) NatureServe provided data analysis review and the global plant association descriptions. The specific technical responsibilities assigned to the cartographic and ecological teams are listed below:

RSGIG responsibilities and deliverables

1. Obtain existing color-infrared aerial photography from NPS
2. Collect photointerpretive observation point data to determine photosignatures, determine a preliminary classification, and familiarize interpreters with plant community characteristics and their range of variation
3. Prepare a preliminary photointerpretation to assist field data gathering efforts
4. Attend a meeting to determine final mapping classes, both vegetated and land use, to be used for the final photointerpretation
5. Interpret aerial photographs
6. Transfer interpreted information to a digital spatial database and produce hard copy (paper) vegetation maps
7. Create digital vegetation coverages including relevant attribute information
8. Conduct field verification of the accuracy of the draft vegetation map
9. Produce Arc/Info export file of photointerpretive observation point locations
10. Provide any ancillary digital files developed during the mapping process
11. Document FGDC compliant metadata files (Appendix A) for all created spatial data

12. Prepare materials for the final report describing procedures used in preparing products

CPRS responsibilities and deliverables

1. Develop a preliminary vegetation classification for the study area from existing data
2. Determine field data sampling locations and strategy
3. Collect field data to identify and describe plant associations in the project area
4. Analyze field data and prepare a final classification, local association descriptions, and a key to plant associations
5. Field test the final classification, descriptions, and plant association key
6. Collect accuracy assessment points, analyze them against the final photointerpretation and prepare statistics describing map accuracy
7. Produce Arc/Info export file of sampling locations, vegetation relevé and accuracy assessment locations, and Access database file of relevé and accuracy assessment data and jpeg image files of relevé photos
8. Develop FGDC compliant metadata files (Appendix A) for all vegetation classification relevés and accuracy assessment observation coverages and databases.
9. Prepare a final report CD with all compiled products

NatureServe responsibilities and deliverables

1. Review vegetation classification developed by CPRS
2. Develop global plant association descriptions
3. Include newly described plant associations into National Vegetation Classification Standard (NVCS) and present on a public web site (www.natureserve.org/explorer/)

A scoping meeting was held in March 1999 at the NPS office in Flagstaff, AZ with all interested parties. The purpose of this meeting was to inform monument staff and interested neighbors about the USGS-NPS Vegetation Mapping Program, learn about the monument's management and science issues and concerns, identify existing data sources, develop a preliminary schedule with assigned tasks, obtain a commitment from the monument to issue collecting permits, identify possible areas of cooperation with neighbors and partners, and define project boundaries.

Park management issues and concerns that a vegetation map could help with were identified during the scoping meeting and included: to identify quaking aspen (*Populus tremuloides*) stands, to better understand the microhabitats and vegetation communities associated with the lava flows, to determine the stand structure of the ponderosa pine (*Pinus ponderosa*) communities, to understand the importance of Bonito Park to Native American communities, and to protect the rare endemic species Sunset Crater Penstemon (*Penstemon cluteii*).

The total mapping area was set at 18,750 acres, including 3,040 acres within SUCR. This boundary was selected in order to include a 1-mile buffer area around the monument and other areas of special interest such as Bonito Park.

Preliminary data collection and review of existing information

To minimize duplication of previous work and to aid in the overall mapping project, we obtained existing data including maps and reports from various sources. Monument staff provided digital and/or hard-copy background maps for the project border and miscellaneous other digital files. We obtained site maps from the NPS and the Coconino National Forest, and topographic maps, digital elevation models (DEMs), digital line graphics (DLGs), and digital raster graphics (DRGs) from the USGS. Babbitt Ranches provided a copy of their recently completed Biological Assessment (Cordasco, et al. 1998). A preliminary list of plant associations and local land use types was prepared following a field reconnaissance survey conducted at the time of the scoping meeting.

Aerial photography and base map acquisition

Aerial photography covering the entire project area was received by RSGIG from USGS/BRD. The color infrared (CIR) photographs were acquired on October 8, 1996 by Merrick, & Company, Aurora, Colorado, and were taken at 1:12,000 (1inch=1,000 feet) scale. Hardcopies of the photographs were provided as 9 inch x 9 inch diapositives. Overlap for these photos averaged approximately 50-60% and sidelap between flight lines is approximately 30-40%. Flight lines for the aerial photos are shown in Figure 8. The team used these photos primarily for delineation of vegetation map classes and secondarily to inform field characterization of the vegetation.

The base maps, standard USGS digital orthophoto quarter quads (DOQQs) for geo-referencing or registration of delineated map classes were created from aerial photographs flown in October 1997. These maps are grayscale, with 1 meter per pixel resolution, UTM coordinate system, and NAD83 datum. The DOQQs used for this project are O'Leary Peak (SE and SW quarter-quads), Strawberry Crater (SW quarter-quad), Sunset Crater East (NW quarter-quad), and Sunset Crater West (NE and NW quarter-quads).

Figure 8. Mapping project area and aerial photo flightlines.

Sampling design development

A gradsect sampling design was used to divide the park into 'environmental types' to stratify for field sampling. The environmental types were developed using habitat types identified in the USDA-FS Terrestrial Ecosystem Survey (TES) mapping (Miller et al. 1991). We also identified, in a scoping session with USGS, BOR, and NPS scientists and managers, four additional aspect and elevation characteristics that could be derived from a Digital Elevation Model (DEM). We developed a digital map (coverage) of environmental types in a GIS by overlaying a coverage of habitat types and the four derived topographic characteristics. The result was 40 possible 'environmental types'. A total of over 100 potential relevé locations were allocated among the environmental types based on the percent contribution of each environmental type to the total study area. The allocated relevés were used to guide sampling. Within the environmental types we initially determined placement of relevés based on road accessibility and land ownership access.

Several environmental types were inaccessible due to extensive sharp lava beds causing high safety risks for the field crew. The Center of Biological Informatics (CBI) lent the field team laser binoculars. The binoculars provide locality information in UTM, using the distance and azimuth offset of targeted locations in conjunction with the GPS Precision Lightweight GPS

Receiver (PLGR) system. Additional laser relevés were completed in SUCR until all environmental types within the gradsect sampling area were sampled.

Field data collection

RSGIG staff conducted field surveys in support of the aerial photointerpretation in June 1999, with some follow-up work to clarify photosignatures in early May 2000. Two RSGIG plant ecologists collected the data and simultaneously took representative photographs of plant associations and their position in the landscape. These observation points were used to describe the plant association characteristics and their occurrence relative to aerial photosignatures. Field notes were transcribed directly on Mylar overlays of aerial photography. The RSGIG team also conducted joint field sessions with CPRS plant ecologists to exchange observations, observe field methodologies for vegetation classification relevé data collection, and discuss the project area.

RSGIG ecologists collected data at 46 photointerpretive observation points to document the plant association characteristics associated with particular photographic signatures. Photointerpretive observation points also helped the photointerpreters understand the range of variation of each plant community. In general, sampling included basic information on habitat and vegetation structure and composition. Specific information recorded included UTM coordinates using the NAD83 datum, dominant species cover data, and a brief summary of environmental characteristics. The datasheet used to collect the photointerpretive observation points can be located in Appendix D.

A two person team of CPRS plant ecologists conducted field surveys from mid-June thru mid-August 1999 and sampled 114 field relevés in the project area. The standard relevé method was used to quantify the vegetation community (Muller-Dombois and Ellenberg 1974, USGS-NPS 2000). The field team subjectively determined field relevé positioning within each environmental type visited so as to represent vegetation assemblages that were relatively dominant, homogenous, and covered a minimum mapping unit area of half a hectare. The field team also sampled special features and unique vegetation types within the environmental assemblages that are of specific interest to the park.

Typically we measured 1,000m² circular relevés; however, in areas of dense vegetation we would lower our relevé size to 400m². We selected 1000m² relevé as our standard as the vegetation of the area is relatively sparse and this size better represents the 0.5ha minimum mapping unit (MMU) than a 400m² relevé (20% vs. 8%). Other vegetation studies of arid lands have also used this relevé size (Thomas et al 2003) and State Heritage ecologists recommended this size for arid and semi-arid vegetation (T. Keeler-Wolf pers. comm.). Additionally, if the patch shape was better represented by rectangular or square relevés we used this relevé layout instead, as in lava bed outcrops. The habitat of the site was characterized by the relevé slope, aspect, elevation, soil characteristics, topographic position, landform type, and whether it was wetland or upland. We also took two photographs that best represented the vegetation of the site and recorded the angles they were photographed from. We documented site UTM coordinates, landownership, and USGS quad. We recorded leaf phenology, leaf type, and physiognomic class for the overall vegetation. For all perennial species we also recorded strata layer (tree, shrub, and ground) and percent species cover. Total cover for all vegetation was estimated for each strata layer (total tree, shrub, and

ground cover). We also measured each tree with >10cm dbh (diameter at breast height). In addition, we included calculations of percent cover for exotic species, individually and combined. Similarly, we measured percent cover for all sensitive species (as identified by the NPS). The classification relevé datasheet is located in Appendix D.

The relevé data was entered into a Microsoft Access 2000 (version 9.0) database. Plant names were standardized to the USDA PLANTS (USDA NRCS 1999) nomenclature. After the data was entered we performed spatial and data entry quality control checks.

Vegetation classification and characterization

Vegetation classification was based on guidelines developed from the National Vegetation Classification (NVC) (TNC and ERSI 1994b) and the National Vegetation Classification Standard (NVCS) adopted by the FGDC (1997). The NVCS classifies vegetation on seven hierarchical levels with the finest levels of the classification being the alliance and the association (Figure 9).

Figure 9. An example of the NVCS physiognomic and floristic hierarchy using the *Pinus ponderosa* / *Bouteloua gracilis* association.

The goal of the USGS-NPS Vegetation Mapping Program is to classify vegetation types to the association level. The definition of an association as put forward by the Ecological Society of America Vegetation Classification Panel is “A vegetation classification unit consistent with a defined range of species composition, diagnostic species, habitat conditions, and physiognomy” (Jennings et al. 2003). Occasionally, a vegetation type cannot be defined to the association level, and the vegetation is described to the courser alliance level. An alliance consists of a group of plant associations that share a uniform physiognomy and is characterized by one or more diagnostic species, which at least one of these species is found in the uppermost vegetation stratum (Mueller-Dombois and Ellenberg 1974).

Associations are named by the dominant and/or indicator species occurring in the community. If more than one species is characteristic of the association, then the species in the dominant strata is listed first and separated by a forward slash (/) from species in the lower strata, or if species occur in the same strata they are separated by a dash (-). Parentheses are used when species are frequently present, but do not necessarily occur all the time, yet are considered an important part of the community structure when present. The nomenclature for alliances is based on the dominant and diagnostic species, and includes at least one species from the uppermost stratum in the alliance name.

Vegetation was initially analyzed using multivariate classification analyses. Matrices of species absolute cover organized by relevé and species were extracted from the field relevé for use in a vegetation classification and ordination software program, PC-Ord, v 4.10 (McCune and Mefford 1999). Six matrices based on division of relevés by lifeform were examined: 1) all relevés, 2) relevés with greater than 60% cover tree species, 3) relevés with greater than 25% (but less than 60%) cover tree species, 4) relevés with greater than 25% cover shrub species (and less than 25% cover tree and herbaceous species), 5) relevés with greater than 25% cover grass and forb species (but less than 25% cover tree or shrub species) and 6) relevés with less than 25% cover. The cover of trees, shrubs or grasses in a relevé was calculated by adding the separate cover estimates for each species of that particular lifeform. Cover estimates needed to be summed, since the total vegetation calculated in the field was based on the strata layer, not on the lifeform. Many species occur in all three strata layers (for example, ponderosa pine commonly occurred in the ground (small saplings), shrub (medium saplings), and tree layer). The percentage used to separate each lifeform type is based on FGDC criteria for NVCS formation classes and as interpreted by NatureServe (Grossman et al. 1998, Reid 2000 pers. comm.). Some relevés had greater than 25% total cover but less than 25% of tree, shrub or herbaceous cover. In those cases the relevé was assigned a formation class based on the dominant lifeform.

We used two different algorithms within PC-Ord to examine species association patterns in each matrix. A divisive method, Two-Way Indicator Species Analysis (TWINSpan), was used to review the relevé. TWINSpan produces a table that classifies sites and species. Initial species and relevé groupings were identified with this step. An agglomerate group averaging method, Unweighted Pair Group Method Using Arithmetic Mean (UPGMA), commonly known as cluster analysis, was next applied with the distance measure defined as Sorensen's coefficient (also known as the Czekanowski or Jaccard coefficient). Each relevé in the cluster analysis was labeled with preliminary alliance and association label based on iterative examination of the cluster analysis graphic output (a dendrogram), preliminary alliance descriptions for the western states (Reid et al. 1999) and the cover values for species in each relevé.

NatureServe reviewed the results of the data analysis, and the initial placement of relevés within associations and alliances. A number of vegetation types identified from the analysis represented associations already documented in the NVCS, and registered in NatureServe Explorer, an online encyclopedia of life (www.natureserve.org/explorer/). In some cases the vegetation types from the analysis did not correspond to existing associations in the NVCS (i.e. appeared to be new associations), and these were treated in three different ways according to the amount of information supporting them from the project. Those with a number of relevés (3-5 or more), or with fewer relevés but covering substantial mapping area were incorporated into the NVCS as

new plant associations. Those with some relevés (typically <3), but seemingly uncommon or of uncertain floristic composition, were designated as “provisional” plant associations in the NVC, and require additional sampling to fully understand their floristic and ecological characteristics. The last group of vegetation types was those represented by only one or two relevés, or that seemed essentially unique to SUCR. Until further inventory is completed, these should be thought of as “local” vegetation assemblages and we describe these throughout the report as local assemblages. A few relevés were classified only to the coarser alliance level.

A dichotomous key to the vegetation association/alliances as well as to the corresponding map classes (described below) was developed prior to the 2001 accuracy assessment field season. The key was used in the 2001 data collection for accuracy assessment. We made slight modifications before using the key in the second round of accuracy assessment data collection during the 2002 field season (Appendix E).

Vegetation map preparation

Four basic elements were used to create the SUCR vegetation map: 1) map class development, 2) aerial photography interpretation, 3) digital transfer, and 4) map validation. Following these steps, a formal accuracy assessment determined errors of omission and commission with the goal of achieving a minimum of 80% map accuracy.

Map class development

A relatively simple vegetation and land use classification was prepared to guide a preliminary aerial photointerpretation, completed by RSGIG in June 1999. CPRS ecologists also used this preliminary work to more fully examine the landscape and vegetation features of the project area during vegetation relevé sampling activities. So as not to bias field researchers, each polygon delineated was given a consecutive number, with attributes for each polygon number listed in a separate table.

Final SUCR map classes used for interpreting the aerial photographs were derived (1) from plant associations described by CPRS, (2) from the Anderson (1976) Level II land use classification system, and (3) from special requests by NPS staff. In some cases, one NVCS association corresponded to one mapping class; more often, because of difficulties in interpreting the CIR photographs, map classes described more than one plant association and were combined into mosaics or complexes of associations. For instance, we combined the two mountain meadow grassland associations (*Bouteloua gracilis* Herbaceous Vegetation and *Muhlenbergia montana* Herbaceous Vegetation) into a Montane Grassland map class. In some instances, NVCS association map classes provided less detail than could be photo-delineated. In these instances, we used modifiers to define and map additional modifiers of vegetation cover and understory species composition (e.g. Ponderosa Pine / Apache Plume Woodland was photo-delineated as >25% total vegetation cover, <25% total vegetation cover, and with >10% pinyon pine). This level of detail provided additional refinement in the map classes; however, only the map class and not the modifier was assessed in the accuracy assessment. The Anderson Level II land use classes included semi-natural vegetation and cultural types, i.e. roads, facilities, residential land, croplands and pastures, etc. Finally, special map classes were created for surficial geology or vegetation types recognized by NPS staff or the photointerpreters, but not part of the NVCS.

These special map classes include Cinder Sparse Mosaic, Lava Beds, and Rock Outcrop and Scree Shrubland.

Aerial photograph interpretation

As a preliminary step prior to actual interpretation, sheets of translucent (single-frosted) Mylar were taped over all of the 9" x 9" photos. The fiducial points (corner and side tics), flight line number, and photograph number were transferred from each photo onto the Mylar using a 0.5 mm lead pencil. Aerial photos and their overlays were backlit on a light table and examined for photographic signatures, using a stereoscope to identify the three-dimensional features. Where photographic signatures were unclear, the diapositives were examined in stereo to make a final determination of the appropriate polygon boundary and/or map class. Only the center portion of each aerial photograph was interpreted, to minimize the effects of edge distortion inherent to 9" x 9" stereo photographs.

The actual interpretation of aerial photographs involved three steps. First, all photos were interpreted into broad classes based solely on standard photointerpretation signature characteristics. These included: tone, texture, color, pattern, topographic position, size, and shadow. Second, field notes and observation points were used to assign the correct map classes. Finally, digital transfer specialists reviewed all of the interpreted photos for consistency and accuracy.

Digital transfer

An ArcInfo GIS database was built for SUCR using in-house protocols for creating vegetation GIS databases. The protocols consist of a shell of Arc Macro Language (AML) scripts and menus that automate the transfer process and insure that all spatial and attribute data are consistent and stored properly. The actual transfer of information from the interpreted aerial photographs to a digital, geo-referenced format involved two techniques. First the Mylar overlays were scanned and warped to fit the DOQQs; second, additional polygons were added using on-screen digitizing with the DOQQs as a background. Both techniques required a background image or base map, in this case the USGS black-and-white DOQQ's. These digital base maps were delivered to RSGIG in November 2000 and data transfer began immediately.

The scanning technique used for SUCR involved a multi-step process whereby the Mylar overlays with their interpreted line work were scanned into a digital image file (.tif file). The digital image file was then converted to a vector file, which was then geo-referenced to the DOQQ base maps. Essential to this process is to match the scale and position of features on the photographs (Mylars) with the scale and position of the same features on the DOQQs. This was accomplished by adjusting the scale of the photo Mylar between numbered control points (Figure 10). AMLs executed the actual manipulation of the vector files until the adjustment was considered a good fit by technicians. Any remaining land use polygons that were not included on the Mylars were transferred through on-screen digitizing. This process enters polygons directly into the GIS database by manually tracing digital lines (using a mouse) on a computer monitor screen with the DOQQ as a background image. Finally, the complete set of digitized line work files were linked into a single file, the polygon topology created, and polygon attribute information added to produce a completed digital coverage.

Figure 10. Aerial photo 4-7 and corresponding (scanned) Mylar overlay.

Map validation

A draft of the vegetation map was printed at the 1:12,000 scale and checked against the interpreted aerial photographs. As an internal accuracy check, we applied photointerpretive observation points over the vegetation map to determine if the map classes matched the field data.

Finally, field verification and revision of the draft map occurred prior to the accuracy assessment analysis. Field trips to validate the map were taken in January and May 2001. These trips included collecting additional photointerpretive observation points and ground-truthing aerial photograph signatures using landmarks and global positioning system (GPS) waypoints. We modified the map classes as a result of field verification and used the modified classes in the final photointerpretation. The final map revision was completed in September 2002.

Accuracy assessment

The CPRS field staff conducted the formal accuracy assessment of the SUCR vegetation map and vegetation association key. We conducted the field surveys in two phases, from August 1 to September 27, 2001 and from October 24 to November 8, 2002. Phase one of sampling was done with a preliminary vegetation map to allow for a majority of accuracy assessment reference points to be collected. Phase two was done with the final vegetation map to ensure that all reference points were collected. Data collection and analysis was done according to standard protocols developed by the USGS-NPS Vegetation Mapping Program, described in the Program Document, Accuracy Assessment Procedures (TNC and ERSI, 1994c) and “USGS-NPS Vegetation Mapping Program: 4.0 Sample Collection for Accuracy Assessment”, 4.4.2 second approach (<http://biology.usgs.gov/npsveg/aa/toc.html>, as of 11/12/2002), and were modified as needed (see below). As is common practice in measuring uncertainty in mapped classes, a sample of locations for each map class, referred to as reference points, were compared to a source of higher accuracy – ground truthing obtained by direct field observation.

Prior to selecting reference points, we checked topology and data structure of the coverage by running a check for node errors and label errors in the GIS dataset. We also dissolved the GIS dataset, removing polygon boundaries when adjoining polygons had the same value using GIS.

Reference point locations were then selected for each map class based on the total cover of each class in the mapping area, where map classes with more cover had more reference points assigned, and vice versa. The number of polygons to be sampled was determined by the number of polygons in each vegetation class and the total area of each vegetation class within the spatial vegetation dataset (Table 1). These standards were determined by USGS-NPS Vegetation Mapping Program criteria to ensure a 90% confidence level. Eight map classes were lumped together for accuracy assessment sampling design and analysis because several map classes were variations of the same plant association (map classes 8-10, 11-12 and 17-19). For example, map class 8 (montane grassland) was lumped together with map class 9 (montane grassland with rabbitbrush) and map class 10 (montane grassland occurring in Bonito Park), and these map classes were treated as a single map class. A table was compiled with vegetation types, the number of polygons and area in hectares for each vegetation type, and the number of polygons to be sampled (Table 1).

Table 1. USGS-NPS Vegetation Mapping Program criteria for sampling numbers for accuracy assessment

Scenario	Description	Polygons in class	Area occupied by class	Recommended number of samples in class
A	Abundant. Many polygons that cover a large area.	≥ 30	≥ 50 ha	30
B	Relatively abundant. Class has few polygons that cover a large area.	< 30	≥ 50 ha	20
C	Relatively rare. Class has many polygons, but covers a small area. Many polygons are close to the MMU.	> 30	< 50 ha	20
D	Rare. Class has few polygons, which may be widely distributed. Most or all polygons are close to the MMU.	$\geq 5, \leq 30$	< 50 ha	5
E	Very rare. Class has too few polygons to permit sampling. Polygons are close to the MMU.	< 5	< 50 ha	Visit all and confirm

We assigned random numbers to polygons for each map class and selected the target number of polygons plus 5 to 10 extra in case targeted polygons could not be accessed. Of the 500 reference points initially chosen, 355 points were sampled in the field in the first phase and 131 in the second phase. We discarded some accuracy assessment points from the initial phase when multiple reference points occurred within a single polygon in the final vegetation map. In such cases, we selected the reference point that contained the largest area of the polygon assessed in the initial round of sampling as the point used for the final round of accuracy assessment.

In the first phase of sampling we used reference points from sampled polygons greater than the minimum mapping unit (MMU) of 0.5 hectares; however, if not enough samples of the map class were available from polygons greater than the MMU, we then sampled polygons less than the MMU. In polygons greater than the MMU, we assigned reference point coordinates randomly in the polygon excluding a 5-meter buffer from the polygon edge (Random Point Generator v.1.1, available at www.ESRI.com (ESRI 2002)). In polygons that were less than the MMU, the centroid of the polygon was used to locate the reference point so as to minimize edge effects from adjacent polygons. We gave the field team a list of UTM coordinates and a radius to survey around the points. In polygons greater than the MMU, a 0.5 hectare area (MMU) was surveyed. In polygons less than the MMU, a radius (less than the MMU) was provided to the field team to ensure that they would not survey in an adjacent polygon and they were to survey the entire radius prior to determining the map class. If the polygon size was less than a 10-meter radius (less than 0.03 hectares), then a polygon map was provided to the field team to orient them within the polygon and the whole polygon was to be surveyed.

In the second phase of sampling, polygons that were equal to or greater than MMU were given a 5-meter buffer from the outside polygon edge. Then a location within the polygon was chosen using a random point generator to add one point to each polygon. We selected the centroid as the sampling point in polygons less than the MMU. For each polygon to be sampled, the field team was provided a polygon map. In polygons greater than the MMU, the field team was to survey an area equivalent to the MMU prior to making a final determination of the map class. In polygons less than the MMU, the entire polygon was surveyed.

Data collection

The CPRS field team had a list of the UTM coordinates for each reference point, the area and perimeter of the polygon encompassing its location, and the shortest distance to an adjacent map class. In the first round of accuracy assessment sampling, polygon shapes were provided for small polygons (<0.5 hectares), which contained a distance scale and direction orientation. In the second round of accuracy assessment sampling, polygon shapes were provided for all polygons that were sampled. The field ecologists recorded accuracy assessment observations on a field form (Appendix D), including the following: the vegetation association/map class within the radius of the reference point, confidence in the decision according to the descriptions of the association/map classes in the field key (using the following four categories: exact, good (some problems), poor, or none that fit), explanation of confidence if less than exact, UTM coordinates (easting, northing), altitude, and GPS error (using the Garmin 45XL, Garmin Corporation, 1996).

During the fieldwork, ongoing discussions between the field ecologists and CPRS plant ecologists allowed for refinement of the plant association/map class key, as well as some of the vegetation classifications. These changes were implemented in the key and may have influenced

the interpretation of the association/map class concepts between the first and second round of sampling. We accounted for these changes during the accuracy assessment analysis described below.

Accuracy assessment analysis

Accuracy assessment statistics were prepared by comparing the map class observed in the field (accuracy assessment observation or reference data) with the map class mapped at the same location on the final vegetation map (map class data). We made these comparisons using both standard accuracy assessment analysis identified as part of the USGS/NPS Vegetation Mapping Program (<http://biology.usgs.gov/npsveg/aa/toc.html>) and a modified ‘fuzzy set’ accuracy assessment analysis (Klopfer et al. 2002). Accuracy assessed observations were overlain onto the final vegetation map to determine the corresponding map class for each location except for those places that were remotely assessed in 2002.

For each standard and fuzzy set comparison, a contingency table was developed to compare the reference data with the map class data. The contingency table lists reference data values in the columns and map class values in the rows. The number of each reference data and map class pair for all sampling locations is located at each row/column intersection in the matrix (see Table 7 for an example). Correct mappings are indicated on the table where the row and column values are the same and typically occur on the diagonal on the matrix (yellow highlight on Table 7). The contingency table is used to calculate a variety of statistics describing the map performance: omission accuracy (also known as producer’s accuracy), commission accuracy (also known as user’s accuracy), the overall accuracy, and the Kappa index.

Initial analysis revealed a low overall accuracy and therefore we examined the errors associated with each observation using a modified ‘fuzzy set’ analysis to rank the type of error (Klopfer et al. 2002, Falzarano and Thomas In Press). In this assessment, we use five criteria (exact match, acceptable error, understandable error, vague similarity, and complete error) to assess the fit between the reference data and map class sampling location (Table 2) (Klopfer et al. 2002). We included only criteria 5, 4, and 3 in our analysis, since criteria 2 and 1 did not provide any additional information to our accuracy assessment analysis.

Table 2. Definitions used in the 'fuzzy set' analysis classifications.

Criteria	Descriptions
5	Exact Match: The reference data is an exact match to the map class.
4	Acceptable Error: If any of the following criteria were met than the case was considered acceptable error: 1) The reference data is the same as a map class in the nearest adjacent polygon and is within 35 meters of that polygon (distance chosen based on project specific considerations), 2) The reference data is in a 2001 polygon that became an inclusion below the MMU in 2002 and had similar floristic and structural composition of the larger 2002 polygon, 3) An alternative correct reference class was described in the field, or 4) The reference class described using the 2001 plant association field key was an alternative map class described using the 2002 map class field key.
3	Understandable Error: The map class has similar structural composition and species dominance.
2	Vague Similarity: The map class has a similar formation type, but not similar species composition.
1	Complete Error: No similarity in the species or structural composition.

A contingency table was created for three criteria: 1) standard or exact match—a correct map class was considered to occur where there was exact match between the reference data and map class data, 2) acceptable error—a correct label was represented by exact (criteria 5) and acceptable (criteria 4) matches between reference data and map class data, and 3) understandable error—a correct label was represented by exact (criteria 5), acceptable (criteria 4) and understandable (criteria 3) matches between reference data and map class data. We would like to point out that the standard accuracy assessment is the same criteria as an exact match in the modified fuzzy set analysis.

An example of acceptable error is the case of a field observation of Cinder Sparse Mosaic mapped as Lava Beds. In this example, the field observation is 25 meters from the nearest polygon, has an error of 15 meters, and that polygon is labeled Lava Bed. We have categorized the classification relevé as acceptable since it is in close proximity to the correct map class and we believe that the apparent misclassification may be a locational error either on the map or in the field rather than a photointerpretation misclassification.

The 2001 vegetation map was developed to vegetation associations (1:1 relationship), however in 2002 the vegetation map was developed to contain aggregates of associations. Concurrently the field key in 2001 was strictly to associations and did not reflect the 2002 map class descriptions. As a result, interpretation of the accuracy of a 2001 classification relevé might be more restrictive than in 2002. For example, consider a classification relevé in 2001 of Apache Plume / Cinder Sparse Vegetation on lava. In 2002 any vegetation association occurring in a lava bed outcrop was defined as Lava Bed Sparse Vegetation, and the map class is Lava Bed Sparse Vegetation. In this case the 2001 observation was acceptable according to the final definitions of map classes.

Another case for acceptable error occurred in the switch between the 2001 and 2002 map. For example, a classification relevé of Montane Grassland was made in 2001 and its location was in a small (10 meter radius) polygon based on the preliminary map. However, on the final map, the sampling location for this classification relevé was found to now be included in a larger polygon (7.5 hectares) labeled Ponderosa Pine / Montane Grass Mosaic. The notes for the original observation described the field situation as small grassland around scattered ponderosa pine. In this case, where the scale of consideration changed, the classification relevé was considered to be an acceptable match to the final map class.

An example of understandable error is if the field observation has a similar species composition and structure as the map class assigned to the polygon containing the observation. For example, Ponderosa Pine / Invasive Herbaceous Vegetation as the reference label and Ponderosa Pine / Montane Grass Mosaic as the map class have the same structure and species composition, except for the understory community. In this case, it is likely that it was difficult for the photointerpreters to delineate the understory community.

Vaguely similar would include the case where the classification relevé (Pinyon Pine - Utah Juniper / Blue Grama Woodland) structure is similar to the map class (Ponderosa Pine / Apache Plume Woodland), however the species composition is not similar. An example of complete error is when the reference label (Ponderosa Pine Invasive Herbaceous Vegetation) has no similarity with the map class (Apache Plume / Cinder Sparse Vegetation) in terms of structure or species composition.

Where the field observation was determined to ‘fit’ the map class for a particular criteria, the field observation was ‘reassigned’ to the map class for the purposes of constructing the error matrix. Hence the diagonals on the error matrix show the sum of all accuracy assessment observation/map class pairs that were matches under the particular criteria being applied.

Overall total accuracy for each contingency table criteria as described above (standard analysis, acceptable error, and understandable error) was calculated by dividing the total number of correctly classified reference data points by the total number of reference data points. Individual map class accuracies were also assessed for each of the criteria described above. To calculate the probability that a reference data observation has been correctly classified (producer’s accuracy or omission error), the number of reference data points correctly classified is divided by the total number of reference data points in that map class. To calculate the probability that the mapped vegetation associations represent the associations actually found on the ground (user’s accuracy or commission error), the number of correctly identified reference samples was divided by the total number of samples classified or mapped to that vegetation association.

Equations to calculate statistics for each criteria described occur in the program document, Accuracy Assessment Procedures (<http://biology.usgs.gov/npsveg/aa/toc.html>) and TNC and ERSI (1994c). Two-tailed, 90% confidence intervals for the binomial distribution were also calculated using JMP statistical software (SAS Institute 1989-2000) using Score Confidence Interval Tables. Score Confidence Interval Tables are known to have better coverage probabilities with smaller sample sizes (Agresti and Coull 1998). To account for correct

classifications due to chance, a Kappa index (Foody, 1992; TNC-ERSI, 1994c) was calculated also using JMP statistical software.

4. RESULTS

Field surveys

We observed forty-six observation photointerpretation sites and 114 classification relevés, including 2 laser obtained relevés (Figure 11). At each classification relevé we took two photos. Information recorded for each relevé and relevé photos are on the project CD (see Appendix A).

Figure 11. Location of photointerpretation observation and classification relevés.

Vegetation classification

The NVCS classification resulted in a total of 12 alliances, 15 associations, and five monument specific local assemblages (Table 3). Full descriptions of the SUCR vegetation associations and provisional associations are located in Appendix F. A listing of all species identified during the course of this study can be found in Appendix G. Five local assemblages were identified as possibly being unique to SUCR; these assemblages need further sampling on the Colorado Plateau to determine if they represent local vegetation types unique to SUCR or if they are found across the landscape. Four alliances and seven associations are newly described in the NVCS. The alliances, as grouped by formation, consist of two forest, three woodland, one shrubland,

four herbaceous, and three sparse alliances. The associations consist of two forest, six woodland, four herbaceous, and three sparse classes. The plant associations, local associations, Anderson land-use classes, and geologic exposures are related to the aerial photointerpretation map classes and are listed in Appendix H. A field key to both the map classes and alliance/association classification is listed in Appendix E.

Unvegetated to sparsely vegetated cinder, lava beds, and rock outcrops are very common in the project area. Although, they are considered a geologic type and are not classified to a NVCS association, they are prevalent and comprise approximately 16% (3,050 acres) of the total area mapped. In some areas lichen cover is high on the lava rocks, and annual vegetation communities, although sparse, are consistent. Annual species and small herbaceous perennial species often include phacelia (*Phacelia* sp.), Newberry's twinpod (*Physaria newberryi*), and blazingstar (*Mentzelia* sp.). Sparsely vegetated shrublands often occur on cinder and lava beds and are most often dominated by wild buckwheat (*Eriogonum corymbosum*) and Apache plume (*Fallugia paradoxa*). Sparsely vegetated areas also often occur as islands of vegetation in lava outcrops. These outcrops may include isolated trees such as ponderosa pine (*Pinus ponderosa*) and quaking aspen (*Populus tremuloides*) as well as groups of shrubs including Apache plume and ocean spray (*Holodiscus dumosus*).

Forests only occur at the highest elevations of the project area and cover less than 1% (72 acres) of the project area. Only one map class (Douglas-fir Forest) is mapped as a forest type. Douglas-fir (*Pseudotsuga menziesii*) can form dense stands on the slopes of O'Leary Peak. Due to high density (crown cover) in some pinyon pine stands, these areas are also classified as forest alliances rather than woodland alliances. However, these dense stands were not mapped separately from the woodland types and were aggregated into the Pinyon Pine – Utah Juniper / Blue Grama Woodland map class.

Woodlands are the predominant vegetation type, covering approximately 60% of the project area (12,548 acres) and occur on all landforms including flats, slopes, hills, drainages, and ridges. Seventy-five of the total 114 relevés sampled were classified as woodlands (Table 3). This includes four alliances and seven associations among the alliances. Three of the associations are newly described. Ponderosa pine woodlands occur most frequently in the park and are found on nearly every landform, except the driest south-facing slopes and at the highest elevations.

Ponderosa pine most often occurs in pure stands; however, it can intermix in areas of high elevation with Douglas-fir or limber pine (*Pinus flexilis*). In drier areas, on south-facing and steep slopes, ponderosa pine can also co-occur with pinyon pine (*Pinus edulis*) and Utah juniper (*Juniperus osteosperma*). Pinyon pine and Utah juniper persist on the dry south-facing flanks of cinder cones and their rims, mountain toeslopes, and lower elevation dry flats. Quaking aspen occurs only in very small stands and patches within the lava beds, in small areas along the lava beds, and in small stands on cinder beds.

Shrublands cover less than 1% (11 acres) of the project area and occur mainly in small patches. Only one map class (Rock Outcrop and Scree Shrubland) was classified as a shrubland type. All of the relevés in this map class were classified as local associations, with unique species composition, and did not have enough data to support classification under the NVCS shrubland formation class. Two of the sparse vegetation map classes are sparse shrublands. Shrubs also often occur in small patches under tree canopy. Shrubs can also co-dominate with grasses in open meadows. Apache plume occurs most frequently in the park and is often associated with ponderosa pine trees. It also occurs in sparse cinder open areas and in lava beds. Other shrubs are also common to these geologic features and include species such as rabbitbrush (*Ericameria nauseosa*), three-leaved sumac (*Rhus trilobata*), ocean spray, pericome (*Pericome caudata*), brickellbush (*Brickellia californica*), and wax currant (*Ribes cereum*). These shrubs also occur on a variety of substrates and landforms.

Grasslands often occur in small patches in or near ponderosa pine woodlands and covers 9% (1,708 acres) of the project area. Blue grama (*Bouteloua gracilis*) and mountain muhly (*Muhlenbergia montana*) are the two most dominant species in these grassland meadow areas. Blue grama is most associated with the lower to mid-elevation areas of the project area and is probably the most common grass species. Blue grama occurs in Bonito Park and in some areas is co-dominant with rabbitbrush. Mountain muhly dominates the upper elevation meadows and often co-dominates with blue grama at mid-elevations. Sand bluestem (*Andropogon hallii*) is a bunchgrass that occurs mostly in sparse patches in the eastern section of the project area and often occurs with ponderosa pine. Western wheatgrass (*Pascopyrum smithii*) is a common understory species in the recently burned areas northwest of the project area. Western wheatgrass was probably used in seed mixes for re-seeding efforts and was found only in the burned areas. Four percent (760 acres) of these grasslands contain recently disturbed areas with evidence of thinning and burning of ponderosa pine. In these areas introduced annual grasses, particularly cheatgrass (*Bromus tectorum*), native forbs such as meadow-rue (*Thalictrum fendleri*) and Carruth's sagewort (*Artemisia caruthii*) and the invasive non-native toadflax (*Linaria dalmatica* ssp. *dalmatica*) and mullein (*Verbascum thapsus*) are common.

Vegetation map classes

A total of 26 map classes, including 5 modifiers, were recognized in the SUCR vegetation map (Table 4). These map classes consist of 21 vegetation classes, including 5 modifiers, and 6 Anderson Level II (Anderson et al. 1976) land-use classes.

Table 4. SUCR Map classes and their NVCS components

Map Code	Map Class	Map Class NVCS Name
1	Cinder Sparse Mosaic	none (Land Cover Class)
2	Lava Beds	none (Land Cover Class)
3	Rock Outcrop and Scree Shrubland	<i>Fallugia paradoxa</i> – <i>Brickellia grandiflora</i> – (<i>Holodiscus dumosus</i>) Scree Shrubland (Local Assemblage), <i>Ericameria nauseosa</i> - <i>Pericome caudata</i> Rock Outcrop Sparse Vegetation (Local Assemblage)
4	Wild Buckwheat - Sand Bluestem Sparse Vegetation	<i>Eriogonum corymbosum</i> - <i>Andropogon hallii</i> Sparse Vegetation
5	Apache Plume / Cinder Sparse Vegetation	<i>Fallugia paradoxa</i> (<i>Atriplex canescens</i> , <i>Ephedra torreyana</i>) Cinder Sparse Vegetation
6	Lava Bed Sparse Vegetation	<i>Pinus ponderosa</i> - (<i>Populus tremuloides</i>) / <i>Fallugia paradoxa</i> - (<i>Holodiscus dumosus</i>) Lava Bed Sparse Vegetation
7	Sand Bluestem Herbaceous Vegetation	<i>Andropogon hallii</i> Colorado Plateau Herbaceous Vegetation
8-10	Montane Grassland (Rabbitbrush, Bonito Park)	<i>Bouteloua gracilis</i> Herbaceous Vegetation, <i>Muhlenbergia montana</i> Herbaceous Vegetation
11-12	Pinyon Pine - Utah Juniper / Blue Grama Woodland (Sparse)	<i>Pinus edulis</i> - (<i>Juniperus osteosperma</i>) / <i>Bouteloua gracilis</i> Woodland, <i>Pinus edulis</i> / Sparse Understory Forest
13	Limber Pine Woodland	<i>Pinus flexilis</i> Woodland Alliance
14	Ponderosa Pine / Cinder Woodland	<i>Pinus ponderosa</i> / Cinder Woodland
15	Ponderosa Pine / Montane Grass Mosaic	<i>Pinus ponderosa</i> / <i>Muhlenbergia montana</i> Woodland, <i>Pinus ponderosa</i> / <i>Bouteloua gracilis</i> Woodland
16	Ponderosa Pine Invasive Herbaceous Vegetation	<i>Pinus ponderosa</i> Wooded Invasive Herbaceous Vegetation (Local Assemblage), <i>Pascopyrum smithii</i> Herbaceous Vegetation
17-19	Ponderosa Pine / Apache Plume Woodland (Pinyon, Sparse)	<i>Pinus ponderosa</i> / <i>Fallugia paradoxa</i> Woodland
20	Ponderosa Pine / Sand Bluestem Woodland	<i>Pinus ponderosa</i> / <i>Andropogon hallii</i> Woodland
21	Douglas-fir Forest	<i>Pseudotsuga menziesii</i> / <i>Muhlenbergia montana</i> Forest, <i>Pseudotsuga menziesii</i> Forest Alliance
22	Transportation, Communications, and Utilities	- none (Anderson Land Use class)
23	Facilities	- none (Anderson Land Use class)
24	Residential Land	- none (Anderson Land Use class)
25	Reservoirs and Trick Tanks	- none (Anderson Land Use class)
26	Strip Mines, Quarries, and Gravel Pits	- none (Anderson Land Use class)
27	Croplands and Pastures	- none (Anderson Land Use class)

Three of the map classes; Montane Grassland (map codes 8-10), Pinyon Pine – Utah Juniper / Blue Grama Woodland (map codes 11-12), and Ponderosa Pine / Apache Plume Woodland (map codes 17-19); were further subdivided by two or three modifiers. These modifiers represent variations of the NVCS vegetation association that were easily mapped and were useful to resource management (for example, map class Montane Grassland is mapped as pure Montane Grassland (map code 8), Montane Grassland with a greater than 10% rabbitbrush (*Ericameria nauseosa*) (map code 9), and Montane Grassland that occurs in Bonito Park (map code 10). The final map classes were determined in a series of meetings among NPS, USGS, and BOR participants using the information obtained from photointerpretation observations, classification

relevés, and preliminary photointerpretation. While the ideal situation is to have each map class correspond to one NVCS plant association, we had to deviate from this in cases where NVCS associations could not be discerned from the aerial photography, such as some of the canopied woodland types. Also, some map classes did not directly correspond to NVCS associations but were included as “park specials” to aid with SUCR’s management needs.

A few of the map classes occurred consistently in patches smaller than the minimum mapping unit (0.5 hectares), particularly Rock Outcrop and Scree Shrubland (map code 3). Because of the importance of these classes for wildlife habitat and monument management priorities, a decision was made to map them where possible regardless of size.

The map classes for SUCR can be described by four categories:

1. NVCS associations represented by a unique photosignature and topographic position (one map class to one plant association)
2. Multiple NVCS associations that together are represented by a unique signature (one map class represents a mosaic of several related plant associations)
3. Stands of vegetation that were not addressed by the NVCS but are seen as management concerns for SUCR and could be recognized on the aerial photography (“park special” map classes)
4. Geologic formations/exposures and land-use classes that are not described within the NVCS

Each map class for SUCR can be crosswalked to their NVCS association using the aggregations described below:

One Map Class to One Plant Association

These map classes were developed by directly translating a NVCS vegetation association into a map class onto the aerial photography.

Map Code	Map Class	NVCS Plant Association
4	Wild Buckwheat - Sand Bluestem Sparse Vegetation	<i>Eriogonum corymbosum</i> - <i>Andropogon hallii</i> Sparse Vegetation
5	Apache Plume / Cinder Sparse Vegetation	<i>Fallugia paradoxa</i> (<i>Atriplex canescens</i> , <i>Ephedra torreyana</i>) Cinder Sparse Vegetation
6	Lava Bed Sparse Vegetation	<i>Pinus ponderosa</i> -(<i>Populus tremuloides</i>) / <i>Fallugia paradoxa</i> -(<i>Holodiscus dumosus</i>) Lava Bed Sparse Vegetation
7	Sand Bluestem Herbaceous Vegetation	<i>Andropogon hallii</i> Colorado Plateau Herbaceous Vegetation

Park Special Map Classes

Only one map class at SUCR is considered a park special. This map class was developed based on local vegetation assemblages identified in the classification relevés.

Map Code	Map Class
	NVCS Plant Association

- 3 Rock Outcrop and Scree Shrubland
Fallugia paradoxa – *Brickellia grandiflora* –(*Holodiscus dumosus*) Scree Shrubland (Local Assemblage)
Ericameria nauseosa - *Pericome caudata* Rock Outcrop Sparse Vegetation (Local Assemblage)

Aerial photograph interpretation

The SUCR project area is represented mostly by sparse vegetation growing from cinder beds, lava flows, and woodlands growing from a number of substrates. The lava flows contain some sparse woodland and shrubland types, but are mostly barren or support a unique flora of lichens and mosses. Cinder beds are both black and red in color, but regardless of color, support sparse forblands, grasslands, and woodlands. Downwind from the pumice mines and near areas subjected to OHV use, the cinder beds are covered by a heavy dust layer.

Interpretation of the late fall, color-infrared aerial photographs for SUCR relied heavily on substrate and landscape position to help determine classes for vegetation polygons since the usual cues of color, shape, and texture were not distinctive for many of the map classes. Long tree shadows were present in the forest and woodland landscapes, partially or completely obscuring the understory. Because the aerial photographs were acquired in October when most of the grass species were dormant, color could not be used to distinguish among the different grassland types. An illustrated guide to the map classes, including a brief description of each map class, its distribution on the landscape, and its photosignature characteristics appears in Appendix H.

GIS database and maps

The SUCR GIS database consists of 11 coverages, 1 basemap imagery file, and associated metadata in ArcInfo format and is archived on a CD (Appendix A) accompanying this report. The coverages and imagery are:

- Accuracy assessment observation points.
- Aspen map. Small photointerpreted aspen (*Populus tremuloides*) patches.
- Classification relevé points.

- d. DOQQ and USGS Quad maps for Sunset Crater, Wupatki, and Walnut Canyon National Monuments.
- e. DOQQ basemap imagery (MrSid images) for SUCR.
- f. Flightline boundary for Sunset Crater, Wupatki, and Walnut Canyon National Monuments.
- g. OHV map. Photointerpreted tracks of off-highway vehicle use.
- h. SUCR park boundary.
- i. Photointerpretative observation points.
- j. Project boundary.
- k. Vegetation map clipped to the National Monument boundary.
- l. Vegetation map for the entire project area. This main product coverage consists of a single Arc Info coverage, developed from a mosaic of 46 aerial photographs (Figure 12), with 1,205 classified polygons covering a total area of approximately 7,590 hectares (18,750 acres). Table 5 shows the total number of polygons and hectares per map class in the project area.

Figure 12. Aerial photograph boundaries

A readme file (Appendix A) further describes these coverages.

A hard copy map was created of the vegetation coverage with a legend identifying the color of each map class. For clarity, the map code was printed only on polygons with an area greater than 5000 m² (0.5 hectare). The hard copy map is presented in a folder sleeve (Appendix I).

Table 5. Map class occurrence in Sunset Crater Volcano National Monument and the environs.

Accuracy assessment

In the 2001 sampling season, 204 accuracy assessment observations were included in the reference data out of the total 334 accuracy assessment observations that were collected. One hundred and thirty-one accuracy assessment observations were eliminated since they represented duplicate observations in polygons in the final vegetation map. In these duplicate cases, the field observation that assessed the largest area of the polygon was selected as the field observation data to be used in the accuracy assessment analysis. For 2002, 130 additional field observations were added to the accuracy assessment reference data making a combined total of 334 reference points for the final accuracy assessment analysis (Figure 13). The final number of reference points analyzed for each map class was representative of the total area of each map class except for map classes with high percentage of occurrence on private land (i.e. land use classes). In these cases, the number of reference points sampled was less than the number suggested for the accuracy assessment analysis.

Figure 13. Location of accuracy assessment field observations for the 2001 and 2002 combined reference data set.

Evaluation of the performance of each map class can provide insight on map error. For each map class we report the criteria at which the class was assessed to meet the standard of 80% or greater for commission and omission accuracy (Table 6).

Standard analysis of map accuracy (criteria 5, exact criteria) suggested that overall accuracy was low, 53.9% (90% confidence interval of 43.7% to 64.1% and a Kappa index of 50.1%, Table 7). For criteria 4, acceptable error, accuracy of the map is 70.3% (90% confidence interval of 69.0% and 84.0%) and Kappa index of 68.0% (Table 8). Criteria 3, understandable error, accuracy is 86.8% (90% confidence interval of 84.1% and 95.4%) and a Kappa index of 85.8% (Table 9). Omission and commission accuracies for each individual map class, including two-tailed, 90% confidence intervals, are also shown for each criteria in each contingency table.

Table 6. Map class performance.

Map Code	Map Class	Commission Accuracy (Criteria and %)	Omission Accuracy (Criteria and %)	Comments
1	Cinder Sparse Mosaic	Acceptable 80%	Understandable 87%	This type is considered adequate as mapped.
2	Lava Beds	Exact 90%	Exact 100%	This type is considered adequate as mapped.
3	Rock Outcrop and Scree Shrubland	Acceptable 100%	Understandable 38%	Omission accuracy remained below the standard even with the least restrictive criteria, indicating that incidences of this type were often omitted from the map. This map class is often less than the minimum map unit in size (84% of all polygons were <.5 ha. in size) so omissions might be expected. Merging this map class into adjacent polygons would increase the accuracy of the overall map, however there is value in having known occurrences mapped.
4	Wild Buckwheat-Sand Bluestem Sparse Vegetation	Understandable 62%	Understandable 76%	36% of this map class occurs below the MMU. When misclassified it was shown on the map as Cinder Sparse Mosaic or Apache Plume / Cinder Sparse Vegetation. Sparse shrub and tall grassland communities (Map classes 4 & 5) may need to be considered as a single map class due to the constraints in photointerpreting them.
5	Apache Plume/Cinder Sparse Vegetation	Acceptable 83%	Understandable 70%	This map class was sometimes misclassified as Wild Buckwheat – Sand Bluestem Sparse Vegetation (omission error), which typically occurs in cinders and has a similar formation type.
6	Lava Bed Sparse Vegetation	Acceptable 83%	Exact 91%	This type is considered adequate as mapped.
7	Sand Bluestem Herbaceous Vegetation	Understandable 83%	Understandable 100%	This type is considered adequate as mapped.
8-10	Montane Grassland	Understandable 71%	Understandable 80%	On the map this class was misclassified as Ponderosa Pine Invasive Vegetation, Ponderosa Pine Montane Grass Mosaic, and Ponderosa Pine Cinder Woodland (omission error). Many polygons of this class interfinger between ponderosa pine dominated canopies. This class was mapped as Rock Outcrop and Scree Shrubland and Wild Buckwheat-Sand Bluestem Sparse Vegetation (omission error) and misclassified as Ponderosa Pine Invasive Vegetation and Montane Grassland (commission error). Small patches of Montane Grassland adjacent to ponderosa pine dominated canopies could be combined into the large-scale ponderosa pine herbaceous understory map classes to increase accuracy.

5. DISCUSSION

The vegetation at SUCR represents the results of primary succession 800 years after the volcanic reshaping of the landscape. This unique environment provided several challenges to vegetation mapping and can be summarized below:

- 1) Sparse vegetation is difficult to photointerpret and classify, especially if the substrate has a strong spectral signal, such as in cinder and lava. A strong spectral signature appears to have reduced the accuracy of mapped ponderosa pine classes with sparse understory communities (i.e. Ponderosa Pine / Apache Plume Woodland was often misclassified as Ponderosa Pine / Cinder Woodland and Ponderosa Pine / Montane Grass Mosaic).
- 2) Many new associations were described in the course of this project. NatureServe usually considered field relevés with less than five occurrences as local assemblages or provisional associations due to no previous data collection. With more extensive vegetation sampling and classification in northern Arizona, some of the types currently described as local assemblages or provisional associations may be assigned association status. Associations were not always the best mapping classes and some associations were aggregated into mosaics (i.e. Ponderosa Pine / Montane Grass Mosaic contains both the *Pinus ponderosa* / *Muhlenbergia montana* Woodland and *Pinus ponderosa* / *Bouteloua gracilis* Woodland association).
- 3) Scale changes between the preliminary map in 2001 and the final map in 2002 influenced the accuracy assessment results. Polygons that were assessed in 2001 when overlaid with the 2002 final vegetation map were found to be significantly different in size and shape. There were more preliminary polygons drawn at less than the MMU on the 2001 map. Project resources did not allow re-sampling of all 2001 data points in order to eliminate all these errors; although we did review each point and eliminated those that were suspected of representing that type of error. These changes resulted in differences in scale assessments of the polygons and probably reduced our overall map accuracy. Two-thirds of the accuracy assessment reference data were obtained in 2001 and showed a total accuracy of 48% using only these points. In 2002 the overall accuracy was 63% (exact criteria) using just 2002 collected reference data. For instance, Apache Plume Cinder Sparse Shrubland often occurred in small openings in ponderosa pine woodlands and was often interpreted as Ponderosa Pine / Apache Plume Woodland depending on the scale of the assessment.
- 4) The field key used for the accuracy assessment was not reviewed by the photointerpreters before accuracy assessment in 2001. It is recommended that all field keys be reviewed by the photointerpreters prior to accuracy assessment.
- 5) The field data collection, 1999, and accuracy assessment, 2001 and 2002, may be measuring land cover characteristics that are different from those shown on the 1996 photography used for map creation. Land surface changes since the 1996 aerial photography may be significant from the 1999 field sampling and the 2001/2002 accuracy assessment. Changes include land use, which caused alteration and development, recreational activities, fire and non-native

plant invasion composition. Seasonal vegetation changes from the time the aerial photographs were acquired (October 1996) to the time classification relevés and accuracy assessment observation points were sampled (summer 1999, 2000, 2001, and 2002) complicated the interpretation, since the dormant vegetation that was evident in the fall presents a different ecological aspect than summer vegetation. The difficulty of this task was increased because of the long shadows in October when both sets of photos were flown. New aerial photography flown near the summer solstice (June 21) would have minimized the shadow problem. Other problems with interpretation and digital transfer arose because the aerial photos and the DOQQs were flown in different years and exhibit different ground conditions. If new photography were used at the start of this project, at the time of this report the database's ground condition would only be three years old, not six years old. During the course of the SUCR vegetation mapping project, the Arizona Department of Transportation began widening U.S. Highway 89, which runs north and south along the western edge of the mapping area. The resulting changes in vegetation were not documented in the October 1996 photography. The highway was being expanded from a narrow two-lane highway to a four-lane highway with turning lanes and acceleration and deceleration lanes (Figure 14). In addition, the highway was widened so that "islands" of native vegetation, typically stands of ponderosa pine with a graminoid understory, remained in the median strip between the northbound and southbound travel lanes.

Figure 14. Photos illustrating reconstruction of portions of U.S. Highway 89.

At the southern end of this highway reconstruction project, the affected plant association is mapped as predominantly ponderosa pine woodlands with a mix of grasses and cinder in the understory. At the northernmost end of the highway reconstruction project the vegetation is montane grasslands and pinyon-juniper woodlands. Given the width of the reconstruction project, it is possible that nearly the entire stand of ponderosa pine was removed, or only a small portion may remain isolated in the median strip. Digital data showing the extent and location of the highway reconstruction was not available at the time we mapped SUCR. Once the highway data become available, the vegetation database should be revised to account for the new road cut and to re-calculate vegetation acreages. These map class changes may occur frequently enough to have caused misclassified polygons and therefore decrease the measured total accuracy assessment.

- 6) Twenty-eight percent of the total number of polygons were mapped at below the MMU. Accuracy assessment of these polygons is problematic due to the high amount of resources needed to correctly locate and assess these polygons. This not only increased the number of required polygons for accuracy assessment but also caused problems in interpretation of some classes. For example, Montane Grassland routinely occurs in small patches

interspersed among ponderosa pine and depending upon the scale of photointerpretation and field evaluation could often be confused with Ponderosa Pine / Montane Grass Mosaic. In addition, under a tree canopy GPS accuracy was often insufficient to conclusively place the field technician within polygons less than 0.5 hectares, particularly when the polygon may have had convoluted shapes.

- 7) The number and variability of vegetation signatures sometimes made them difficult to distinguish and interpret consistently. Environmental factors such as moisture gradients, slope exposure, presence and density of exotic grasses and forbs, and soil diversity result in several photographic signatures for each grassland and some shrub and woodland classes. Aerial photograph signatures in the ponderosa pine types were challenging to interpret because of dense mats of ponderosa pine litter and heavy layers of dust generated from pumice mining operations and recreation vehicle trails. Both conditions created a photosignature similar to that of dormant blue grama grass. Photography flown when the grass was green would have aided in distinguishing litter and dust from grass. Extensive ground reconnaissance and a number of accuracy assessment observation points were used to determine where the understory consisted of grasses or other herbaceous species versus mats of pine litter (Figures 15).

Figure 15. Typical ponderosa pine stands with pine litter and graminoid understories.

- 8) Color photography flown with more appropriate timing for this mapping project would have eliminated many of the problems and delays this project experienced. For example, RSGIG technicians spent a great deal of time trying to locate registration points on the aerial photos and the DOQQs.

Vegetation classification and map classes

Over 25% of the alliances and 35% of the associations were newly defined during the course of this project; the remainder was described as local assemblages described during the course of this project or incorporated into existing community classification. Most of the diversity of associations occurred within the woodland formation class. Ten of the 17 associations were directly translatable into map classes; the remaining associations were combined to form mosaics of vegetation as a map class. Additional detail in land use, canopy cover and associated species was photo-delineated for three of the associations and this additional detail was represented as map class modifiers. While the modifiers provided additional important information to the map, for accuracy assessment only map classes and not modifiers were analyzed.

Forests in the SUCR project area are not common. Although the term “ponderosa pine forest” is commonly used to describe the vegetation communities in the park, most of the ponderosa pine dominated areas have less than 75% canopy cover and contain a more open park-like canopy structure. Only in small patches at higher elevations on Darton Dome and O’Leary Peak does Douglas-fir and pinyon-pine forest canopy ever reach these cover values. Downslope these community types gradate quickly into a more open woodland-like formation. Therefore, most of our tree dominated vegetation communities fall within the sparser woodland communities.

Woodlands are represented mainly by ponderosa pine associations. The average tree cover for these associations is often a sparse 15% canopy cover. Although ponderosa pine associations throughout their range typically contain higher cover, at SUCR the primary successional environment limits tree establishment and growth rates. In fact, most of the ponderosa pine trees at SUCR have bent, distorted and exposed roots suggesting high environmental stress with deep cinder limiting seedling development. The ponderosa pine communities tend to have a few large trees and a sparse understory. These sparse understory species were difficult to distinguish on the aerial photography.

Only one NVCS shrubland alliances was defined in this project; the remaining shrublands were described in the sparse lifeform or as local shrubland stands. Due to the sparse patchiness of the landscape, and the large scale 1,000m² relevés, true shrublands were a minor type sampled. A mosaic, Rock Outcrop and Scree Shrubland, map class was developed to describe many of the small sparse stands of shrubs. As well, a sparse Apache Plume community often occurred in small patches in cinder barrens and in gaps of the ponderosa pine woodlands.

Five herbaceous associations were described and aggregated into three mappable classes. These were combined due to difficulty separating them in the photointerpretation. Most of the herbaceous associations were sampled using a small scale relevé (400m²), due to the density of the vegetation in these communities. Even after combining the communities, they were often misidentified on the map. Montane grasslands were often misclassified as invasive herbaceous types and vice versa. This problem not only stems from misinterpretation in the photo-delineation process, but from seasonal changes in herbaceous plant communities. It is likely that an area that had an invasive photosignature in 1996 no longer maintained the same species composition during the 2001 and 2002 field season. These errors represent a lapse of time between the photo acquisition and the project completion.

Although only two associations and one local assemblage were defined as sparse vegetation associations, many of the relevés placed in the woodland and herbaceous lifeforms contain less than 25% total vegetation cover. In order to not artificially proliferate associations based solely on their cover values they were combined based on similarities of their species composition and the cover ranges described for each association. The distinction between sparse communities and alternate placement in a woodland, shrub or herbaceous class is still under general review in the NVCS. At the time of classification only seven sparse alliances were represented in the NVCS classification. Further park classification work may have different standards and recommendations and may result in an altered placement of relevés than was determined in the course of this study.

The USGS-NPS vegetation mapping projects are designed to produce both a vegetation classification and a set of map classes. Typically the systems are very similar, but sometimes there is not a strict one-to-one correspondence between the two. Photographic interpretation is based on the ability to accurately and consistently delineate map classes based on complex signatures. Vegetation characteristics that can be seen on aerial photography are not necessarily the same as those apparent on the ground and vice versa. Field reconnaissance and map verification work by the photointerpreters aided enormously in developing the map classes and discerning the inherent variability of each photographic signature. Close collaboration between the mappers and the ecologists doing the classification was critical to each understanding the concepts behind the plant associations and map classes.

Accuracy assessment

The USGS-NPS park mapping program has the standard of 80% overall map accuracy and for each class. The map did not meet this accuracy using the exact (53.9%) or acceptable (70.3%) accuracy criteria, but it did using the understandable criteria (86.8%). The acceptable accuracy best describe the functional map accuracy and while it is lower than the standard, we believe the map is usable as long as the assessments for each individual map class are reviewed and are kept in mind when the map is being used for management purposes. Most of the error in the map can be directly attributed to known sources and not to gross error in photointerpretation.

Applications

The vegetation map is ready for use with the knowledge that some of the map classes are below the desired 80% accuracy. These map classes may need to be aggregated depending on the desired accuracy needed for a particular project. Map classes can be aggregated to the NVCS alliance level or to the lifeform.

This map will provide the baseline vegetation data that will allow for better resource management of the park. As with other USGS-NPS park management programs, it is possible that this map will assist with many different aspects of planning activities, including fire management planning, habitat modeling, field sampling for threatened and endangered species, research of particular species and their habitats, education and interpretation, and trail maintenance. This study will also help to compare habitats across management boundaries and hopefully to assist in the joint-agency management of the lands studied in the project environs. Ultimately, the vegetation map will help to monitor impacts on vegetation health as well as the overall ecosystem health of the area.

7. GLOSSARY

The following people contributed to this glossary: Alan Bell, Jack Butler, Daniel Cogan, Janet Coles, Doug Crawford, Dave Eckhardt, Monica Hansen, and Tom Owens.

This glossary refers to terms as they are used in USGS-NPS vegetation mapping projects. Some terms may not appear in this report.

7.5-Minute Quadrangle. Informally known as a 'quad' map. A USGS paper map product at 1:24,000 scale covering 7.5 minutes of latitude and 7.5 minutes of longitude. Features shown include elevation contours, roads, railroads, water bodies, buildings, urban developments, wooded cover, permanent ice fields, and wetlands. This is a basic layer of information for many ecological and natural resource applications. A digital version of a 7.5-minute quad is called a Digital Raster Graphic (DRG).

Accuracy. The closeness of results of observations, computations, or estimates to the true values or to values that are accepted as being true (ASP 1984). See also Error.

Accuracy Assessment (AA). The process of determining the thematic accuracy of the vegetation map. An unaffiliated ecologist tests map accuracy after the vegetation mapping and classification are complete. (Stadelmann et al. 1994).

Accuracy Assessment Point. A location where accuracy assessment data are collected. See "Producing rigorous and consistent accuracy assessment procedures" at <http://biology.usgs.gov/npsveg/aa/aa.html> for more information.

Aerial Photography. Photography taken from an airplane (not satellite) mounted with

specially designed photographic equipment. Ideally, the lens and the film are parallel to the surface being photographed. A sequence of aerial photographs along a flight line will have a certain amount of overlap so that the photos can be viewed with a stereoscope. "Sidelap" refers to overlap between flight lines (ASP 1984). Print size is usually 9"x9" and are photos that may use true color or color infrared film.

Alliance. A physiognomically uniform group of associations sharing one or more diagnostic (dominant or indicator) species that usually occur in the uppermost stratum of the vegetation (FGDC 1997). This is the second finest level in the NVCS hierarchy.

Anderson Classification System.

A classification system developed for use with remote sensing systems in the 1970s adopted for the National Vegetation Classification Standard to map cultural and water features (Anderson et al. 1976).

Level I	Level II
Urban or Built-up Land	Residential
	Commercial and Services
	Industrial
	Transportation, Communications, and Utilities
	Industrial and Commercial Complexes
	Mixed Urban or Built-up Land
	Other Urban or Built-up Land
Agricultural Land	Cropland and Pasture
	Orchards, Vineyards, and Ornamental Horticultural Areas
	Confined Feeding Operations
	Other Agricultural Lands
Water (non-vegetated portion)	
	Streams and Canals
	Lakes

	Reservoirs
	Bays and Estuaries
Barren Land	
	Dry Salt Flats
	Beaches
	Sandy Areas other than Beaches
	Strip Mines, Quarries, and Gravel Pits
	Transitional Areas
	Mixed Barren Lands

ArcInfo. A geographic information software used to view and analyze data.

Association. The finest level of the NVCS classification hierarchies. A physiognomically uniform group of stands of vegetation that share one or more diagnostic overstory and understory species. These elements occur as repeated patterns of assemblages across the landscape, and are generally found under similar habitat conditions (FGDC 1997).

Attribute (digital data). A numeric, text, or image data field in a relational database table (such as a GIS) that describes a spatial feature such as a point, line, polygon, or cell (ESRI 1994).

Automation. The process of entering data into a computer (see also Digitize).

Base map. The control to which all spatial data is georeferenced. Interpreted photo data are transferred to a base map to rectify and register the data. In this project the base maps are USGS DOQQs.

Bureau of Reclamation (USBR, BOR).

A U.S. Department of Interior agency created in 1902 and charged with developing environmentally and economically sound irrigation and hydropower projects in 17 Western States. The Remote Sensing and

GIS Group of the BOR manages a number of park projects for the USGS-NPS Vegetation Mapping Program.

Biological Resources Discipline (BRD). A USGS discipline housing the Center for Biological Informatics. The BRD's mission is to work with others to provide the scientific understanding and technologies needed to support the sound management and conservation of our Nation's biological resources. Formerly, the National Biological Service (NBS).

Center for Biological Informatics (CBI). A USGS Science Center. CBI serves as the operating agent for the National Biological Information Infrastructure. In addition, CBI manages the USGS-NPS Vegetation Mapping Program along with other national data collection programs that complement and strengthen its role within the NBII.

Class. The level in the NVCS hierarchies based on the structure of the vegetation. Class is determined by the relative percentage of cover and the height of the dominant, uppermost life forms (Grossman et al. 1998).

Classification Accuracy. How closely the map classes match the vegetation found on the landscape. This is determined by accuracy assessment protocols. See "Producing rigorous and consistent accuracy assessment procedures" at <http://biology.usgs.gov/npsveg/aa/aa.html> for more information.

Color Infrared (CIR) Film. A three-layer color film sensitized to green, red, and near-infrared portions of the spectrum. CIR films emphasize differences in infrared reflectance from surfaces and are some of the most useful aerial films currently available for use in agricultural and vegetation surveys. The images are sharper and have better contrast

than conventional color photos because they are less susceptible to atmospheric light scattering. Furthermore, CIR has a high transmission component through green leaves, meaning that it can detect layers of leaves lower in the canopy. In true-color photography, the photosynthetic pigments within leaves quickly absorb visible light, and the film records information about nothing below the uppermost leaf layer. Color differences recorded on CIR film are used to differentiate among vegetation types. Generally, in spring and summer, healthy deciduous trees and other vegetation photographs as magenta or red, while healthy evergreens photograph more as a brownish red. CIR film can only be used in daylight.

Commission Accuracy. See Producer's Accuracy.

Community. An assemblage of species that co-occur in defined areas at certain times and have the potential to interact with one another (Grossman et al. 1998). In the NVCS, Association and Community are synonyms.

Community Element Global (CEGL). NatureServe's unique plant association coding system in their central biodiversity database; also known as Elcode.

Community Type. See Association or Type.

Complex. A group of associations that are not distinguishable from one another on aerial photography and so are grouped into a map class. Compare with Mosaic.

Confusion Matrix. See Contingency Table.

Contingency Table. A table that is used in accuracy assessment to determine the degree of misclassification that has occurred. The

table compares the classes derived from accuracy assessment relevés to the classes derived from photointerpretation. Also referred to as Error Matrix, Confusion Matrix, or Misclassification Matrix.

Coordinate System. A reference system that represents horizontal and/or vertical locations and distances on a map. A geographic coordinate system is the latitude and longitude with respect to a reference spheroid. A local coordinate system is one that is not aligned with the Earth's surface. Most coordinate systems are based on projections of the earth's surface onto a plane. All spatial data in this project uses the Universal Transverse Mercator (UTM) coordinate system.

Cover. The area of ground covered by the vertical projection of the aerial parts of vegetation (FGDC 1997).

Cover Type. A designation based upon the plant species forming a plurality of composition within a given area (e.g., Oak-Hickory) (FGDC 1997). It is roughly equivalent to an Alliance in the NVCS classification hierarchy.

Coverage. A data theme in a geographic information system with vector and polygon topology and attribute data related to that topic. Also, the file format used by Arc/Info software for vector spatial data.

Cowardin Classification. A wetland classification system used as the FGDC standard for wetland classification (Cowardin et al. 1979).

Crosswalk. The relationship between the elements of two classification systems. For example, this project includes a crosswalk between Map Classes and units of the

NVCS. In a database, the crosswalk is in a Lookup Table (LUT).

Cultural Vegetation. Vegetation planted or actively maintained by humans such as annual croplands, orchards, and vineyards. Contrast with Natural Vegetation.

Datum. A mathematical model that describes the shape of the earth. The earth is not a sphere but is rather an ellipsoid distorted by rotation about its axis, bulging at the equator and flattened at the poles. Because of the distribution of continents and seas, the distortion is not uniform around the globe and there are datums for different parts of the earth based on different measurements (Snyder 1982). The datum used by this project is NAD83.

Datum (horizontal-control). The position on the spheroid of reference assigned to the horizontal control of an area. A datum may extend over an entire continent or be limited to a small area (referred to as 'local datum'). This project used the North American Datum of 1983 (NAD83) (ASP 1984).

Density. Density is the relationship between the area covered by the vegetation and the total area of a polygon in which the community is found. The USGS-NPS Vegetation Mapping Program uses a series of arbitrarily defined density classes to separate vegetation units: Closed/Continuous > 60 %, Discontinuous 40-60%, Dispersed 25-40%, Sparse 10-25%, Rare 2-10%. Compare with Pattern and Height.

Diagnostic Species. A species generally considered to indicate (i.e., diagnose) a specific set of environmental conditions. For example, the presence of *Vaccinium stamineum* var. *stamineum* (gooseberry) beneath a canopy of chestnut oak, black oak, and Virginia pine indicates that the site is

dry. The trees can inhabit a wide range of sites, wet to dry, but the gooseberry understory is the indicator of a drier habitat. Sometimes also called Indicator Species (FGDC 1997).

Dichotomous Field Key. A document that identifies plant associations or map classes on the basis of pairs of exclusive characteristics such as "forested" versus "non-forested". This key is an important product of each vegetation-mapping project. Also known as Vegetation Field Key and Vegetation Key.

Digital Orthophoto Quadrangle (DOQ). A USGS digital product derived from high altitude aerial photography. Each DOQ is rectified and registered to locations on the earth and covers the same area as a 7.5 minute quad. These are often used as base maps to register photointerpreted data. See also Quarter Quadrangle.

Digital Raster Graphic (DRG). A scanned image of a paper USGS topographic quadrangle map. The geographic information is georeferenced to the UTM projection with the same accuracy and datum as the original map. The minimum scanning resolution is 250 dots per inch.

Digitize. The process of converting lines on a map or image into a computer file. The basic technique involves tracing a line with a device connected to a computer that sends a stream of x-y coordinates corresponding to the traced line into a computer file. Synonymous with Automation.

Division. The highest level in the NVCS hierarchy, separating the earth's surface into vegetated and non-vegetated categories (FGDC 1997). (See NVCS).

Dominance. The extent to which a given species or life form dominates in a community because of its size, abundance or cover. The ecological assumption is that dominant species can affect the fitness of associated species (FGDC 1997).

Dominant Life Form. An organism, group of organisms, or taxon that by its size, abundance, or coverage exerts significant influence upon an association's biotic and abiotic conditions (FGDC 1997).

Ecological Groups. Non-NVCS categories of vegetation based on plant assemblages, physical environments, and dynamic processes useful for conservation planning. These groups are classified on total floristic composition, physiognomy (vertical structure), distribution (horizontal structure), physical environment (slope, rainfall), chemical variables (soil pH), and disturbance regimes. Some factors are difficult to measure directly, and must be inferred from knowledge of species ecology, spatial patterns, and ecological processes.

Edge Distortion. In reference to aerial photographs, lens distortion increases with distance from the center of the photograph. Because of this, photointerpreters work only with the center third of each aerial photograph.

Error. The numeric distance of results of observations, computations, or estimates from the values that are accepted as being true. Also refers to the misclassification of thematic data. Contrast with Accuracy.

Error Matrix. See Contingency Table.

Existing Vegetation. The plant species existing at a location at the present time. The USGS-NPS Vegetation Mapping Program

classifies and maps existing vegetation. Contrast with Potential Vegetation

Federal Geographic Data Committee (FGDC). Coordinates the development of the National Spatial Data Infrastructure (NSDI). The NSDI encompasses policies, standards, and procedures for agencies to produce and share geographic data. The 17 federal agencies that make up the FGDC are developing the NSDI in cooperation with state, local, and tribal governments, the academic community, and the private sector.

Field Reconnaissance. Preliminary field visits by photointerpreters and vegetation ecologists to gain an overview of the vegetation of the project area and how it relates to the NVCS.

Flight Line. A line connecting the principal points of sequential vertical aerial photographs. Designated on the film as 'flight line number – photo number' (ASP 1984).

Floristics. The kinds, number and distribution of plant species in a particular area.

Formation. A level in the NVCS hierarchies that represents vegetation types sharing a definite physiognomy or structure within broadly defined environmental factors, relative landscape positions, or hydrologic regimes (Grossman et al. 1998).

Frequency. The number of occurrences of an item of interest.

Georeference. The process of converting a map or image into real-world coordinates. A non-georeferenced map or image is said to be in 'digitizer-inches' or 'scanner-inches', i.e., it has no real-world coordinates.

Geographic Information System (GIS).

An organized database of geographically referenced information (ESRI 1994).

Global Positioning System (GPS). A system of satellites, ground receiving stations and handheld receivers that allow accurate location of features on the earth's surface. GPS receivers are used to locate field relevés, reconnaissance points, and accuracy assessment points.

Gradsect. Gradient directed transect sampling. The gradsect sampling design is intended to provide a description of the full range of biotic variability (e.g., vegetation) in a region by sampling along the full range of environmental variability. This approach is based on the distribution of vegetation along environmental gradients. Transects that contain the strongest environmental gradients in a region are selected in order to optimize the amount of information gained in proportion to the time and effort spent during the vegetation survey (Grossman et al. 1994).

Ground photograph. An image recorded with the photographer standing on the ground (See Aerial Photography).

Ground truth. The process of taking aerial photographs into the field to see how particular photographic signatures compare with the vegetation on the ground.

Group. The level in the NVCS hierarchies based on leaf characters and identified and named in conjunction with broadly defined macroclimatic types to provide a structural-geographic orientation (Grossman et al. 1998).

Habitat. The combination of environmental or site conditions and ecological processes influencing a plant community.

Habitat Type. 1. A collective term for all parts of the land surface supporting, or capable of supporting, the same kind of climax plant association (Daubenmire 1978). 2. An aggregation of land areas having a narrow range of environmental variation and capable of supporting a given plant association (Gabriel and Talbot 1984).

Hectare. A metric unit of measure equal to 10,000 m² or approximately 2.471 acres.

Height. Height of the overstory of a plant community. One of the physiognomic modifiers classified in the USGS-NPS Vegetation Mapping Program. Vegetation polygons are attributed by height class: < 0.5 m, 0.5-2 m, 2-5 m, 5-15 m, 15-35 m, 35-50 m, >50 m. Compare with Density and Pattern.

Indicator Species. See Diagnostic Species.

Infrastructure. Human-built systems that include structures such as roads and bridges, water supply systems, and electric, gas or telephone lines.

Integrated Taxonomic Information System (ITIS). A comprehensive, standardized reference for the scientific names, synonyms and common names for all the plants and animals of North America and the surrounding oceans. This database is accessible over the Internet (<http://www.itis.usda.gov/>). The PLANTS database is an important ITIS partner providing plant taxonomic information to ITIS.

Land Cover Classification.

A classification of the cultural, physical, and vegetation features that cover the earth, commonly used with remote sensing technology. The Anderson Classification System is a land cover/land use classification.

Vegetation classification is a subset of land cover classification.

Land Use Classification. A classification of the earth's surface that defines the human use the land is providing. Commonly used with remote sensing technology, and usually combined with land cover classification. Natural vegetation may be classified as "vacant", "forest", or "grazing".

Large-scale. Refers to a map or image with a large-scale denominator (e.g., 1:100,000). Large-scale maps cover a broad area, are usually low in detail, and images usually have low resolution (e.g., 30m per pixel).

Look-Up Table (LUT). A computer file that is a list of standard elements that may be entered in a field in the database. In the context of these vegetation-mapping projects, LUT relates the elements of one classification to another in a crosswalk. The values of a map classification could be related to the associations of the NVCS in a park project.
